The correlation of brain size to body size does not tell the whole story of human brain evolution, however. In Figure 45.2, which compares the brains of four vertebrates, we see that the forebrain is larger than other brain regions, and in mammals this is seen as an elaboration of the cerebral cortex. If we look just at mammals, another feature is the degree of *convolution* of the cortex. Since the cortex is a layered, two-dimensional array of neurons, the area of cortex is increased by convolutions, which are greatest in humans. And finally, the percentage of the cortex that is association cortex (i.e., devoted to the integration of information) is by far the greatest in humans. It is these evolutionary changes, primarily in the cortex, that provide the resources for the great intellectual capacity of humans—a topic to which we will return at the end of the chapter.

47.9 Evolution of the Human Brain Brain size scales to body size across a wide range of vertebrates. The higher primates have larger brains than predicted by the correlation, and humans stand outside this relationship with much bigger brains. The increase in brain size in humans is mostly due to an increase in the cerebral cortex. The human brain is also highly convoluted, and more of it is devoted to associative functions.

47.1 RECAP

The central nervous system communicates with the rest of the body through the peripheral nervous system. We are conscious of some sensory information coming into the CNS, but are not conscious of other afferent information used in physiological regulation. Different regions of the brain have specific functions. Evolution of the human brain has resulted in a greatly increased cerebral cortex devoted to integration of information.

- Explain how the major functional divisions of the nervous system relate to their origins in the embryonic neural tube. **See pp. 986–988 and Figure 46.2**
- Trace the information flow that results in a spinal reflex. **See pp. 988–989 and Figure 46.3**
- Describe the spatial relations and functions of the major divisions of the telencephalon. **See pp. 990–992 and Figure 47.5**
- What distinguishes the human brain from the brains of other mammals? **See p. 992 and Figure 47.9**

Now that you have some knowledge of the structure and function of different regions of the nervous system, let's explore some examples of how information is processed in the neural circuitry in some specific regions.

47.2 How Is Information Processed by Neural Networks?

Specific functions are localized in specific parts of the nervous system and depend on the neural circuits, or networks, in those structures. A major focus of modern neuroscience is understanding how the various functions of the nervous system, ranging from simple reflexes to complex learning and memory, are accomplished by the interactions of neurons in circuits. Let's look at two examples of how neural networks process information: the autonomic nervous system (an output pathway) and the visual system (an input pathway).

The autonomic nervous system controls involuntary physiological functions

The **autonomic nervous system**, or **ANS**, comprises the output pathways of the CNS that control involuntary functions, such as heart rate, sweating, and some functions of the gut. Its control of diverse organs and tissues is crucial to homeostasis. The ANS has two divisions, **sympathetic** and **parasympathetic**, that work in opposition to each other in their effects on most organs: one division causes an increase in an activity and the other a decrease. The sympathetic and parasympathetic divisions of the ANS are easily distinguished by their anatomy, their neurotransmitters, and their actions (**Figure 47.10**).

The best-known functions of the ANS are those of the sympathetic division that produce the fight-or-flight response: increasing heart rate, blood pressure, and cardiac output and preparing the body for emergencies (see **Figure 41.5**). In contrast, the parasympathetic division slows the heart and lowers blood pressure; its actions have been characterized as “rest and digest.” It is tempting to think of the sympathetic division as speeding things up and the parasympathetic division as slowing things down, but it is not that simple; for example, the sympathetic division slows down the digestive system whereas the parasympathetic division accelerates it.

Whether sympathetic or parasympathetic, every autonomic efferent pathway begins with a *cholinergic neuron* (one that uses acetylcholine as its neurotransmitter) that has its cell body in the brainstem or spinal cord. These cells are called *preganglionic neurons* because the second neuron in the pathway with which they synapse resides in a collection of neurons outside the CNS called a *ganglion*. The second neuron is called a *postganglionic neuron* because its axon extends out from the ganglion. The axon of the postganglionic neuron synapses with cells in the target organs (see **Figure 47.10**).

The postganglionic neurons of the sympathetic division are called *noradrenergic* because they use norepinephrine (also known as noradrenaline) as their neurotransmitter. In contrast, the postganglionic neurons of the parasympathetic division are mostly cholinergic. In organs that receive both sympathetic and parasympathetic input, the target cells respond in opposite ways to norepinephrine and to acetylcholine. This happens, for example, in a region of the heart called the *pacemaker*, which generates the heartbeat. Stimulating the sympathetic nerve to the heart or dripping norepinephrine onto the pacemaker cells increases their firing rate and causes the heart to beat faster. In contrast, stimulating the parasympathetic nerve to the heart or dripping acetylcholine onto the pacemaker cells decreases their firing rate and causes the heart to beat more slowly.

The sympathetic and parasympathetic divisions of the ANS can also be distinguished by anatomy. The preganglionic neurons of the parasympathetic division come from the brainstem and the *sacral* region; those of the sympathetic division come from the *thoracic* and *lumbar* regions (see **Figure 47.10**). Most of the ganglia of the sympathetic division are lined up in two chains, one on either side of the spinal cord. The parasympathetic ganglia are close to the target organs.

A specialization of the sympathetic division is its innervation of the adrenal gland, which is critical for the fight-or-flight response. The preganglionic sympathetic neuron sends its axon all the way out to the adrenal gland. The medulla (core) of the gland is composed of hormone-secreting cells that are really developmentally modified postganglionic sympathetic neurons that have lost their axons, and they secrete their “neurotransmitters” (epinephrine and norepinephrine) into the extracellular fluid, from which they enter the circulation and act as hormones (see **Section 41.1**).

The ANS is an important link between the CNS and many physiological functions. Its control of diverse organs and tissues is crucial to homeostasis. Despite its complexity, work by neu-

PARASYMPATHETIC DIVISION

SYMPATHETIC DIVISION

47.10 The Autonomic Nervous System The autonomic nervous system is divided into the sympathetic and parasympathetic divisions. The two divisions work in opposition to each other in their effects on most organs; one results in an increase and the other a decrease in activity.

robiologists and physiologists over many decades has made it possible to understand its functions in terms of neuronal properties and circuits.

Patterns of light falling on the retina are integrated by the visual cortex

The visual system is one of the most studied input pathways to the central nervous system. In Section 46.4 we described how light falling on the retina produces signals that are transmitted through the cellular circuits of the retina, resulting in action po-

tentials in the optic nerve. But, how does the CNS use this information to reconstruct the visual world in the brain? The experiments that have investigated this question are some of the most famous experiments in neurobiology and have resulted in Nobel Prizes.

RETINAL RECEPTIVE FIELDS One aspect of the processing of visual information through the retina is the *convergence of information*. Each human retina contains over 100 million photoreceptors but only about 1 million *ganglion cells*. It is the axons of the ganglion cells that communicate information from the eyes to the brain. How is the information from so many photoreceptors integrated by the many fewer ganglion cells?

This question was addressed in classic experiments by Stephen Kuffler at Johns Hopkins University in 1953. He used electrodes to record the activity in the axons of single ganglion cells of cat eyes while stimulating the retinas with spots of light (**Figure 47.11**). These experiments were the starting point for understanding how the brain assembles information from single cells to create visual images—in other words, of how the brain sees.

Kuffler's experiments revealed that each ganglion cell has a well-defined **receptive field** composed of a group of photoreceptor cells that receive light from a small area of the entire visual field. Stimulating these photoreceptors with light activates the ganglion cell, which sends action potentials to the thalamus and on to the visual cortex (the area of the occipital lobe where visual information is processed; see Figure 47.5). Information from many photoreceptors is therefore communicated to the brain as a single message. However, individual photoreceptors may contribute to the receptive fields of multiple ganglion cells, so that receptive fields overlap.

The receptive fields of most ganglion cells are circular, but whether a spot of light falling on a receptive field excites or inhibits its ganglion cell depends both on the nature of the receptive field and on where the spot of light falls on it. Receptive fields have a *center* and a concentric *surround*, and can be either *on-center* or *off-center*. Light falling on the center of an on-center receptive field excites the ganglion cell, and light falling on the center of an off-center receptive field inhibits the ganglion cell. Light falling on the surround has the opposite effect: the surround for an on-center receptive field inhibits the ganglion cell, and the surround for an off-center field is excitatory. Thus the activity of the ganglion cell reflects how much of the light stimulus is on the center and how much is on the surround of its receptive field (see Figure 47.11).

Center effects are always stronger than surround effects. Thus a small dot of light directly on the center of a receptive field has the maximal effect, and a larger light stimulus illuminating the center and parts of the surround has a smaller effect. A uniform patch of light falling equally on the center and surround has very little effect on the firing rate of the ganglion cell for that receptive field.

How are cells in the retina connected to each other to create receptive fields? The photoreceptors in a receptive field's center are connected to the associated ganglion cell by *bipolar cells*. The photoreceptors in the surround modify communication between the center photoreceptors and their bipolar cells through the lateral connections of *horizontal cells* and *amacrine cells* (see Figure 46.21). Thus, the receptive field of a ganglion cell results from a pattern of synapses between photoreceptors, horizontal cells, amacrine cells, and bipolar cells. A general lesson to learn from this seemingly confusing chain of events is that inhibition can be as important as excitation in neural circuits.

In summary, the neural circuitry of the retina results in the generation of signals in the axons of the optic nerve to the brain that communicate simple information about the patterns of light and dark falling on different parts of the retina. But once the action potentials in the optic nerve reach their destinations, how does the brain integrate them to construct visual images of the outside world?

RECEPTIVE FIELDS OF CELLS IN THE VISUAL CORTEX The axons of the optic nerves terminate in a region of the thalamus that is a relay station receiving information from both the right and left eyes. From the thalamus, the information encoded in the activity of axons in the optic nerves is relayed to the visual cortex in the occipital lobes at the back of the brain. In the 1960s, David Hubel and Torsten Wiesel of Harvard University studied the activity of neurons in the visual cortex by shining spots and bars of light on retinas while recording the activities of single cells in the cortex. They found that neurons in the visual cortex, like retinal ganglion cells, have receptive fields. For their pioneering work in visual neurophysiology, Hubel and Wiesel received the Nobel prize in 1981.

Receptive fields of neurons in the visual cortex, however, differ from the circular receptive fields of retinal ganglion cells. Neurons in the visual cortex called *simple cells* are maximally stimulated by bars of light with a particular orientation falling on a small region of the retina. These simple cells receive input from several ganglion cells whose circular retinal receptive fields are lined up in a row, creating a bar of sensitivity.

Other cells in the visual cortex are called *complex cells*. These cells responded maximally to bars of light with particular orientations, but the bars can fall anywhere on a large area of retina. Thus the receptive field of a complex cell appears to be due to that cell receiving inputs from several simple cells that share a certain stimulus orientation but have receptive fields in different locations on the retina (**Figure 47.12**). Some complex cells respond most strongly when the bar of light moves in a particular direction.

The concept that emerges from these experiments is that the brain assembles a mental image of the visual world by analyzing edges in patterns of light falling on the retina. Each retina sends a million axons to the brain, but there are *hundreds of millions* of neurons in the visual cortex. The action potentials from one retinal ganglion cell are received by hundreds of cortical neurons, each responsive to a different combination of orientation, position, color, and movement of contrasting lines in the patterns of light and dark falling on the retina.

INVESTIGATING LIFE

47.11 What Does the Eye Tell the Brain?

Stephen Kuffler's experiments recorded the activity in the axons of single ganglion cells in the eyes of cats. These groundbreaking experiments revealed the existence of a circular receptive field for each of the retina's ganglion cells. Signals from photoreceptor cells in a receptive field are either excitatory or inhibitory to the ganglion cell, which sends action potentials via the optic nerve to the brain.

HYPOTHESIS Retinal ganglion cells are excited or inhibited by light and dark stimuli falling on local areas of the retina.

METHOD

1. Place electrodes in the optic nerve of a cat.
2. Stimulate the retina with different combinations of light and dark stimuli and record the responses of ganglion cell axons.
3. Continue recording and move the stimuli around the retina to find the area of sensitivity—the receptive field—for a specific ganglion cell.

RESULTS

Stimulus patterns on retina

Action potentials in on-center ganglion cell

Action potentials in off-center ganglion cell

Complete darkness

Small spot falling on center of receptive field

Large spot covering receptive field

Ring of light excluding center of receptive field

An on-center ganglion cell is maximally stimulated by light falling on its receptive field's center and is inhibited by a ring of light falling on its receptive field's surround.

An off-center ganglion cell is maximally stimulated by light falling on its receptive field's surround and is inhibited by light falling on its center.

CONCLUSION Ganglion cells use a center-surround dichotomy to encode patterns of contrast between light and dark.

INVESTIGATING LIFE

47.12 Cells in the Visual Cortex Respond to Specific Patterns of Light

Torsten and Wiesel showed that information from light falling on the circular receptive fields of ganglion cells (see Figure 47.11) converges on the visual cortex's simple cells, which have linear receptive fields. These simple cells transmit information to complex cells in the cortex, which in turn respond to linear stimuli falling on different areas of the retina.

HYPOTHESIS Signals from light falling on receptive fields of the ganglion cells elicit responses from cells in the visual cortex.

METHOD

RESULTS

Ganglion cells communicate with thalamic cells that relay information to the visual cortex. The area stimulated by each bar of light includes the receptive fields of several ganglion cells.

CONCLUSION Cells in the retina, thalamus, and cortex are connected in such a way as to respond to specific patterns of light.

Cortical cells receive input from both eyes

How do we see objects in three dimensions? The quick answer is that a person's two eyes, located at the front of the head, see overlapping, yet slightly different, visual fields—that is, humans have **binocular vision**. A person who is blind in one eye has great difficulty discriminating distances. Animals whose eyes are on the sides of the head have minimal overlap in their fields of vision and, as a result, poor depth vision; however, they can see predators creeping up from all sides.

The story of how the brain integrates information from two eyes begins with the paths of the optic nerves. The two optic nerves run along the underside of the brain, join just under

the hypothalamus, and then separate again (**Figure 47.13A**). The place where they join is called the **optic chiasm**. Axons from the half of each retina closest to your nose cross in the optic chiasm and go to the opposite side of your brain. The axons from the outer half of each retina do not cross over at the optic chiasm; axons from the outer left retina go to left side of the brain, and vice versa for axons from the outer right retina.

The functional consequence of the optic chiasm is that all of the visual information from the left side of your field of vision when you are looking straight ahead goes to the right side of your brain, and all of the visual information from the right side

47.13 Anatomy of Binocular Vision (A) Each eye transmits information to both sides of the brain; however, the right side of the brain processes all information from the left visual field (red), and the left side of the brain processes all information from the right visual field (green). (B) The visual cortex sorts visual field information according to whether it comes from the right or left eye.

of your field of vision goes to the left side of your brain. These relationships are shown in red and green in Figure 47.13A.

Cells in the visual cortex are organized in stripes and columns. Stripes refer to the organization across the surface of the cortex, and columns to the organization through the depth of the cortex (**Figure 47.13B**). Stripes and columns alternate according to the source of their input: left eye, right eye, left eye, right eye, and so on. Cells closest to the border between two stripes or columns receive input from both eyes and are therefore called *binocular cells*. Binocular cells interpret distance by measuring the *disparity* between the points at which the same stimulus falls on the two retinas.

What is disparity? Hold your finger out in front of you and look at it, closing one eye and then the other. Your finger appears to jump back and forth, because its image falls on a different position on each retina. Repeat the exercise with a distant object. It doesn't jump back and forth as much, because there is less disparity in the positions of the image on the two retinas. Certain binocular cells respond optimally to a stimulus falling on both retinas with a particular disparity. Which set of binocular cells is stimulated depends on how far away the stimulus is.

When we look at something, we can detect its shape, color, depth, and movement. Where does all this information come together? Is there a single cell that fires only when a red sports car drives by? No. Specific visual experience comes from simultaneous activity in a large collection of cells. In addition, most visual experiences are enhanced by information from the other senses and from memory, which helps explain why about 75 percent of the cerebral cortex is association cortex.

47.2 RECAP

Information in the nervous system is processed by cellular interactions in neural networks. The opposing actions of the sympathetic and parasympathetic divisions of the ANS can be understood in terms of neural pathways consisting of just two neurons. Vision involves a more complex interaction of neurons, organized into receptive fields, to process patterns of light and dark falling on the retina.

- Describe the anatomical and functional differences between the sympathetic and parasympathetic divisions. **See p. 993 and Figure 47.10**
- Explain the cellular basis for the receptive fields of retinal ganglion cells. **See p. 995 and Figure 47.11**
- How do cells in the visual cortex get information about how far away an object is? **See pp. 997–998 and Figure 47.13**

By studying the neural circuitry of the visual system and the ANS, you have gained some understanding of how information reaches the CNS and how the CNS controls various functions of the body. But what about the higher functions of the mammalian CNS—the complex functions between input and output, such as language, learning, memory, and dreams?

47.3 Can Higher Functions Be Understood in Cellular Terms?

The higher brain functions discussed in the remaining pages of this chapter are undeniably complex. Nevertheless, neuroscientists, using a wide range of techniques, are making considerable progress in understanding some of the cellular and molec-

ular mechanisms involved in those processes. The following discussion addresses several aspects of brain and behavior that present challenges to neuroscientists: sleep and dreaming, learning and memory, language use, and consciousness.

Sleep and dreaming are reflected in electrical patterns in the cerebral cortex

A dominant feature of behavior is the daily cycle of sleep and waking. All birds and mammals, probably all other vertebrates, and also many invertebrates, sleep. We humans spend one-third of our lives sleeping, yet we do not know why or how. We do know, however, that we need to sleep. Loss of sleep impairs alertness and performance. Many people in our society—certainly most college students—are chronically sleep-deprived. Every day, accidents and serious mistakes that endanger lives can be attributed to impaired alertness caused by lack of sleep. Insomnia (difficulty in falling or staying asleep) is one of the most common medical complaints.

THE ELECTROENCEPHALOGRAM A common tool of sleep researchers is the **electroencephalogram**, or **EEG** (Figure 47.14A). Rather than recording the activity of single neurons, the EEG characterizes activity in huge numbers of neurons. EEG electrodes are much larger than the very fine electrodes used to detect single cell activity. Placed at different locations on the scalp, EEG electrodes record changes in the electric potential differences between electrodes over time. These differences reflect the electrical activity of the neurons in the brain regions under the electrodes, primarily regions of the cerebral cortex. Usually the electrical activity of one or more skeletal muscles is also recorded on the chart; this record is called an *electromyogram*

(EMG). Movements of the eyes are recorded as an *electrooculogram* (EOG).

EEG, EMG, and EOG patterns reveal the transition from being awake to being asleep. They also reveal that there are different states of sleep. In mammals other than humans, two major sleep states are easily distinguished: **slow-wave sleep** and **rapid-eye-movement (REM) sleep**. Slow-wave sleep gets its name from the high-amplitude, slow-frequency waves in the EEG. REM sleep gets its name from jerky movements of the eye-balls that occur during this state. In humans, sleep states are characterized as non-REM sleep and REM sleep. Human non-REM sleep has four stages, of which only the two deepest stages are considered true slow-wave sleep.

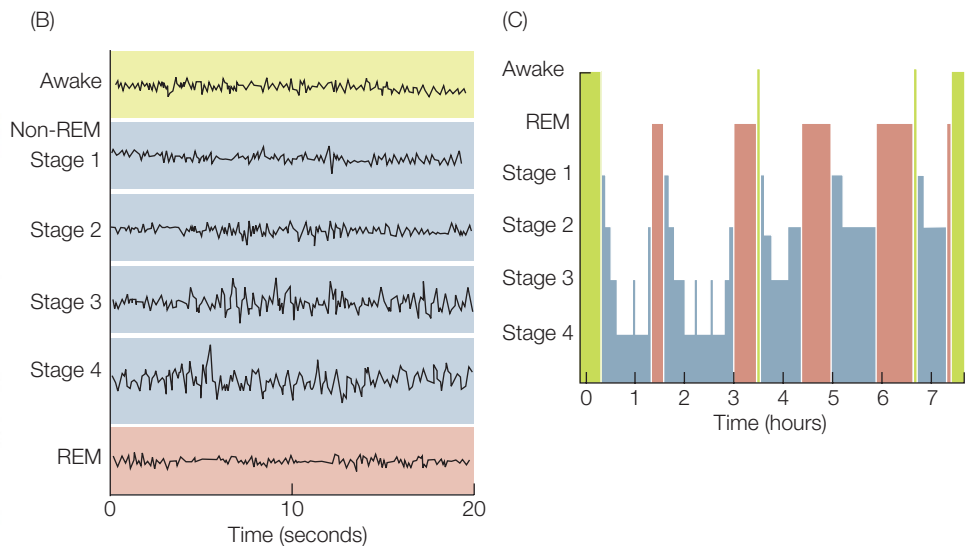

When you fall asleep at night, the first sleep state entered is stage 1 non-REM sleep, which then progresses through stages 2, 3, and 4 (Figure 47.14B). Stages 3 and 4 are deep, restorative, slow-wave sleep. This first full cycle of non-REM sleep is followed by an episode of REM sleep. Throughout the night, you experience four or five cycles of non-REM and REM sleep (Figure 47.14C). About 80 percent of your sleep is non-REM sleep. Vivid dreams and nightmares occur during the 20 percent of sleep that is REM sleep.

CELLULAR CHANGES DURING SLEEP When we are awake, several nuclei in the brainstem reticular formation are continuously active. Axons from neurons in these nuclei extend to the thalamus and throughout the cerebral cortex, where they release depolarizing neurotransmitters (acetylcholine, norepinephrine, and serotonin). These broadly distributed neurotransmitters keep the resting potential of the neurons of the thalamus and cortex close to threshold and sensitive to synaptic inputs, thereby maintaining the responsiveness of the brain that characterizes being awake.

(A)

47.14 Stages of Sleep (A) Electrical activity in the cerebral cortex is detected by electrodes that are placed on the scalp and record changes in voltage between the electrodes through time. (B) The resulting record is an electroencephalogram, or EEG. (C) Humans cycle through different stages of sleep throughout the night.

With the onset of sleep, activity in these brainstem nuclei decreases, and their axon terminals release less neurotransmitter. With the withdrawal of the depolarizing neurotransmitters, the resting potentials of the cells of the thalamus and cortex become more negative (hyperpolarized), and the cells are less sensitive to excitatory synaptic input. Their processing of information is inhibited, and consciousness is lost.

An interesting neural event happens as a result of the hyperpolarization with the onset of sleep: cells begin to fire action potentials in bursts. The synchronization of these bursts over broad areas of cerebral cortex results in the EEG slow-wave pattern that characterizes deep non-REM sleep. Studies of neurons of the thalamus and cortex have shown that their hyperpolarization during non-REM sleep is due to increased opening of K^+ channels, and that bursting is due to Ca^{2+} channels whose inactivation gates close rapidly and require hyperpolarization to be reopened. We can therefore explain the EEG pattern of non-REM sleep in terms of the properties of neurons and ion channels.

At the transition from non-REM to REM sleep, dramatic changes occur. Some of the brainstem nuclei that were inactive during non-REM sleep become active again, causing a general depolarization of cortical neurons. Thus in REM sleep the synchronized bursts of firing cease, and the EEG resembles that of the awake brain. Because the resting potentials of the neurons return to near threshold levels, the cortex can process information, and vivid dreams occur.

So, why don't we act out our dreams? During REM sleep the brain inhibits both afferent (sensory) and efferent (motor) pathways; we are paralyzed during REM sleep. Limb twitches and the jerky eye movements are motor signals breaking through the inhibition. The bizarre nature of dreams may be due to the lack of sensory feedback to the cortex from the body and the outside world. In other words, a functioning cortex is out of touch with reality. The function of muscle paralysis during REM sleep may be to prevent the acting out of dreams.

Knowing the cellular mechanisms of sleep has not yet led to an understanding of its function. Many questions remain. Why do we have two sleep states with very different neurophysiological characteristics? Why does non-REM sleep always occur first? Why do the two states cycle during the rest period? We know sleep is essential for life, but we don't know why. One set of hypotheses is that sleep is necessary for the maintenance and repair of neural connections and for the neural changes involved in learning and memory—and possibly forgetting. These hypotheses are supported by many experiments showing that performance of a learned task or recall of declarative information on the day following training is impaired if sleep is prevented, and is best following a good night's sleep.

Language abilities are localized in the left cerebral hemisphere

No aspect of brain function is as integrally related to human consciousness and intellect as language. Therefore, brain mechanisms that underlie the acquisition and use of language are extremely interesting to neuroscientists. A curious observation about lan-

guage ability is that it resides in one cerebral hemisphere—which in 97 percent of people is the left hemisphere. This phenomenon is referred to as the *lateralization* of language functions.

Fascinating research on this subject was conducted by Roger Sperry and his colleagues at the California Institute of Technology. The two cerebral hemispheres are connected by a tract of white matter called the *corpus callosum*. In one severe form of epilepsy, bursts of action potentials travel between hemispheres via the corpus callosum. Cutting the tract eliminates the problem, and patients function well following surgery. However, these “split-brain” subjects display interesting deficits in language ability.

After the surgery, if an object is shown in the right visual field and the left eye is closed (see Figure 47.13), the patient can describe it verbally and in writing. If the object is shown in the left visual field and the right eye is closed, the patient cannot describe it verbally or in writing, but can use his left hand to point to a picture of it. Lacking the connecting tissue between the two hemispheres, knowledge or experience of the right hemisphere can no longer be expressed in language.

Individuals who have suffered damage to the left hemisphere are frequently left with some form of **aphasia**, a deficit in the ability to use or understand words. Studies of such individuals have identified several language areas in the left hemisphere.

- **Broca's area**, located in the frontal lobe just in front of the primary motor cortex, is essential for speech. Damage to Broca's area results in halting, slow, poorly articulated speech or even complete loss of speech, but the patient can still read and understand language.
- **Wernicke's area**, located in the temporal lobe close to its border with the occipital lobe, is more involved with sensory than with motor aspects of language. Damage to Wernicke's area can cause a person to lose the ability to speak sensibly while retaining the abilities to form the sounds of normal speech and to imitate its cadence. Such a patient cannot understand spoken or written language.
- The **angular gyrus**, located near Wernicke's area, is believed to be essential for integrating spoken and written language.

Normal language ability depends on the flow of information among various areas of the left cerebral cortex. Input from spoken language travels from the auditory cortex to Wernicke's area (**Figure 47.15A**). Input from written language travels from the visual cortex to the angular gyrus to Wernicke's area (**Figure 47.15B**). Commands to speak are formulated in Wernicke's area and travel to Broca's area and from there to the primary motor cortex. Damage to any one of those areas or the pathways between them can result in aphasia. Using modern methods of brain imaging, it is possible to see the metabolic activity in different brain areas when the brain is using language (**Figure 47.16**).

Some learning and memory can be localized to specific brain areas

Learning is the modification of behavior by experience. *Memory* is the ability of the nervous system to retain what is learned and

47.15 Language Areas of the Cortex Different regions of the left cerebral cortex participate in the processes of (A) repeating a word that is heard and (B) speaking a written word.

yourBioPortal.com

GO TO Web Activity 47.2 • Language Areas of the Cortex

experienced. Even very simple animals can learn and remember, but these two abilities are most highly developed in humans. Consider the amount of information associated with learning a language. The capacity of memory and the rate at which memories can be retrieved are remarkable features of the human nervous system.

LEARNING Learning that leads to long-term memory and modification of behavior must involve long-lasting synaptic changes. A phenomenon that may explain how long-term synaptic changes might arise is long-term potentiation, or LTP (see Figure 45.18). LTP results from high-frequency electrical

stimulation of certain identifiable circuits that makes these circuits more sensitive to subsequent stimulation. In contrast, continuous, repetitive, low-level stimulation of these same circuits reduces their responsiveness, a phenomenon that has been called **long-term depression (LTD)**. LTP and LTD may be fundamental cellular or molecular mechanisms involved in learning and memory.

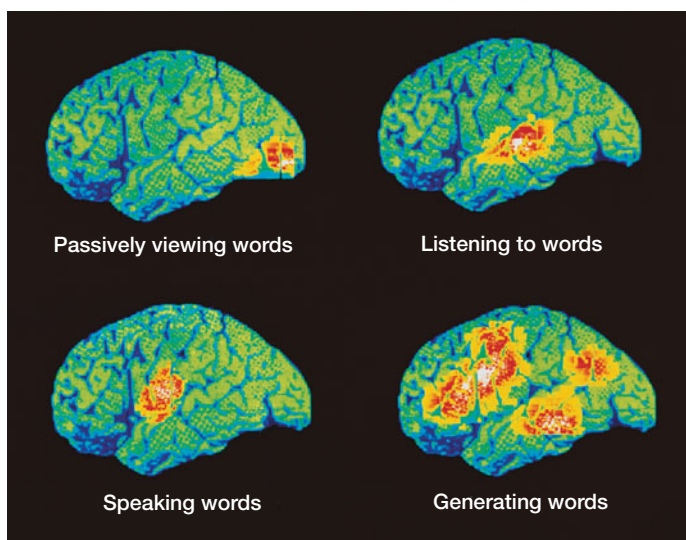

Several kinds of learning exist. A form that is widespread among animal species is **associative learning**, in which two unrelated stimuli become linked to the same response. The simplest example of associative learning is the **conditioned reflex**, described by the Russian physiologist Ivan Pavlov. Pavlov observed that a dog salivates at the sight or smell of food—a simple autonomic reflex. He discovered that if he rang a bell just before food was presented to the dog, after a few trials the dog would salivate at the sound of the bell, even if no food followed. The salivation reflex was conditioned to be associated with the sound of a bell, a stimulus that normally is unrelated to feeding and digestion. Experiments in the laboratory of Richard Thompson, now at University of Southern California, located for the first time the circuitry for a conditioned reflex, and it is in the cerebellum.

More complex forms of learning, often referred to as “observational learning” are the foundation of human intelligence. The general pattern of successful observational learning has three elements:

- We pay attention to another person's behavior.
- We retain a memory of what we have observed.
- We try to copy or use that information.

47.16 Imaging Techniques Reveal Active Parts of the Brain

Positron emission tomography (PET) scanning reveals the brain regions activated by different aspects of language use. Radioactively labeled glucose is given to the subject. Brain areas take up radioactivity in proportion to their metabolic use of glucose. The PET scan visualizes levels of radioactivity in specific brain regions when a particular activity is performed. The red and white areas are the most active.

A key to this scheme of learning is the way in which we create and recall memories.

MEMORY Some of the first insights into memory processes came from clinical treatment of patients with severe epilepsy, a disorder characterized by uncontrollable, local increases in neural activity. The resulting *seizures* can endanger the afflicted individual. Serious cases of epilepsy are sometimes treated by destroying the part of the brain from which the surge of activity originates. To find the right area, the surgery is done under local anesthesia, with the patient remaining conscious. As different regions of the brain are electrically stimulated with electrodes, the patient reports the resulting sensations. Stimulation of some regions of the association cortex elicit recall of vivid memories. Such observations provided the first evidence that specific areas in the brain are associated with specific memories and that memory can be attributed to networks of neurons. Destroying a small area of the brain does not completely erase a memory, however, so it is postulated that memory is a function distributed over many brain regions and can be stimulated via many different routes.

You experience several forms of memory everyday. You have **immediate memory** for events that are happening now. Immediate memory is almost perfectly photographic, but it lasts only seconds. **Short-term memory** contains less information but lasts longer—on the order of 10 to 15 minutes. If you are introduced to a group of new people, you may remember most of their names for 5 or 10 minutes, but you will have forgotten them in an hour or so if you have not repeated them, written them down, or used them in a conversation. Repetition, use, or reinforcement by something that gets your attention (such as the title “president”) facilitates the transfer of short-term memory to **long-term memory**, which can last for days, months, years, or a lifetime.

Knowledge about neural mechanisms for the transfer of short-term memory to long-term memory has come from observations of persons who have lost parts of the limbic system, notably the hippocampus. A famous case is that of the man identified as H.M., whose hippocampus on both sides of the brain was removed in 1953 in an effort to control severe epilepsy. After the surgery, H.M. was unable to transfer information to long-term memory. If someone was introduced to him, had a conversation with him, and then left the room for several minutes, when that person returned, H.M. did not recognize him—it was as if the conversation had never taken place. Up until his death 55 years later, H.M. remembered events that happened before his surgery but could not remember postsurgery events for more than 10 or 15 minutes.

Memory of people, places, events, and things is called **declarative memory** because you can consciously recall and describe them. **Procedural memory** cannot be consciously recalled and described; it is the memory of how to perform a motor task. When you learn to ride a bicycle, ski, or use a computer keyboard, you form procedural memories. Although H.M. was incapable of forming declarative memories, he could form procedural memories. When taught a motor task day after day, he could not recall the lessons of the previous day, yet his perform-

ance steadily improved. Thus procedural learning and memory must involve mechanisms different from those used in declarative learning and memory.

Memories can have considerable emotional content. As mentioned earlier, the limbic system plays a major role in controlling emotions. The amygdala, a component of the limbic system, is necessary for the emotion of fear and the formation of fear memories. As we saw in the opening to Chapter 45, patients with a damaged amygdala do not associate fear reactions with their declarative memories. Memories can also have positive emotional content, and recalling those memories activates parts of the brain known to be associated with pleasurable sensations and reward, as revealed by brain imaging technologies.

We still cannot answer the question “What is consciousness?”

This chapter has only scratched the surface of the organization and functions of the human brain. Even with all of our knowledge of the human brain, and with all of the sophisticated new research tools, we still cannot answer the question “What is consciousness?”

The word “consciousness” is used in everyday language to refer to being awake in contrast to being asleep or in a coma. Here we are referring to the deeper meaning of being mentally aware of yourself, your environment, and events going on around you in such a way that you can plan for future events and make decisions based on experience, evidence, value systems, and predicted consequences. Speculations about consciousness have been the realm of philosophers, but we are getting closer to a neurobiological understanding.

The central requirement for conscious experience is a perception of self that can be integrated with information from the physical and social environment and information from past experience. The basis for a perception of self derives from the huge amount of somatosensory and visceral information that comes from all parts of the body. In the CNS of all vertebrates, this information is used for motor control and for homeostatic regulation. It enables animals to find food, seek mates, seek warmth, avoid cold, avoid danger, and so on. This afferent information goes to appropriate control and regulatory systems in the brainstem and forebrain.

In addition, some of this information goes to somatosensory areas of the cerebral cortex, so the animal is aware of certain information in the sense that it responds to it behaviorally. Visceral afferent information goes beyond its regulatory and control centers in the brainstem and hypothalamus to an area deep within the forebrain called the *insular cortex*, or *insula*. The insula appears to integrate physiological information from all over the body to create a sensation of how the body “feels.” Thus, when an animal’s actions restore homeostasis, it “feels” better, and this is motivation to do the right thing for well-being.

In humans and the great apes, the insula is greatly expanded and has even acquired new types of spindle-shaped neurons not seen in other animals. The circuitry involving the insula has also

evolved to communicate with parts of the brain that are involved in planning and decision making. In imaging studies, the insula is seen to be active in a great diversity of situations that involve strong feelings, be they pleasure, disgust, humor, pain, lust, craving, humiliation, guilt, or empathy. Damage to the insula causes apathy, loss of ability to enjoy music, loss of sexual response, and even loss of the ability to distinguish good food from spoiled food. Humans and the few other species that have expanded insulas and the new spindle cells are the only species that can recognize themselves in a mirror. Could it be that this very discrete part of our brains and its circuitry are the neurobiological bases for self-awareness and conscious experience?

47.3 RECAP

Even complex functions of the nervous system are beginning to be understood in terms of the properties of neurons and neural networks.

- What events in the brain are associated with wakefulness and the stages of sleep? [See p. 999](#)
- Why do some neurobiologists think that the insular cortex might be involved in conscious experience? [See p. 1002–1003](#)

CHAPTER SUMMARY

47.1 How Is the Mammalian Nervous System Organized?

- The brain and spinal cord make up the central nervous system (CNS); the cranial and spinal nerves make up the peripheral nervous system (PNS).
- The nervous system can be modeled conceptually in terms of the direction of information flow and whether we are conscious of the information. The afferent component carries information from the PNS to the CNS, and the efferent component directs information from the CNS to the peripheral parts of the body. [Review Figure 47.1](#)
- The vertebrate nervous system develops from a hollow dorsal neural tube. The brain forms from three swellings at the anterior end of the neural tube, which become the **hindbrain**, the **midbrain**, and the **forebrain**. The forebrain develops into the **cerebral hemispheres** (the **telencephalon**, or **cerebrum**) and the underlying **thalamus** and **hypothalamus** (which together compose the **diencephalon**). The midbrain and hindbrain develop into the brainstem and the **cerebellum**. [Review Figure 47.2](#)
- The spinal cord communicates information between the brain and the rest of the body. It can issue some commands to the body without input from the brain. [Review Figure 47.3](#), [ANIMATED TUTORIAL 47.1](#)
- The **reticular system** is a complex network that directs incoming information to appropriate brainstem **nuclei** that control autonomic functions, and transmits the information to the forebrain that results in conscious sensation. The reticular system controls the level of arousal of the nervous system, including sleep and wakefulness.
- The **limbic system** is an evolutionarily primitive part of the telencephalon that is involved in emotions, physiological drives (such as hunger or thirst), instincts, and memory. [Review Figure 47.4](#)
- The cerebral hemispheres are the dominant structures of the human brain. Their surfaces are layers of neurons called the **cerebral cortex**. The cerebral hemispheres can be divided into the **temporal**, **frontal**, **parietal**, and **occipital lobes**. Many motor functions are localized in parts of the frontal lobe. Information from many sensory receptors projects to a region of the parietal lobe. Visual information projects to the occipital lobe, and auditory information projects to a region of the temporal lobe. [Review Figures 47.5, 47.6, and 47.7](#), [WEB ACTIVITY 47.1](#)

47.2 How Is Information Processed by Neural Networks?

- The **autonomic nervous system (ANS)** consists of efferent pathways that control the physiological function of organs and

organ systems. Its **sympathetic** and **parasympathetic** divisions are characterized by their anatomy, neurotransmitters, and effects on target tissues. [Review Figure 47.10](#)

- The neural network of vision involves patterns of light falling on **receptive fields** in the retina. Receptive fields have a center and a surround, which have opposing effects on ganglion cell firing. [Review Figure 47.11](#), [ANIMATED TUTORIAL 47.2](#)
- Information from retinal ganglion cells is communicated via the optic nerve to the thalamus and then to the visual cortex. The visual cortex seems to assemble an image of the visual world by analyzing edges of patterns of light. [Review Figure 47.12](#)
- **Binocular vision** is possible because information from both eyes is communicated to binocular cells in the visual cortex. These cells interpret distance by measuring the disparity between where the same stimulus falls on the two retinas. [Review Figure 47.13](#)

47.3 Can Higher Functions Be Understood in Cellular Terms?

- Humans have a daily cycle of sleep and waking. Sleep can be divided into **rapid-eye-movement (REM) sleep** and **non-REM sleep**. Deep non-REM sleep is known as slow-wave sleep because of its characteristic EEG patterns. [Review Figure 47.14](#)
- Language abilities are localized mostly in the left cerebral hemisphere, a phenomenon known as lateralization. Different areas of the left hemisphere—including **Broca's area**, **Wernicke's area**, and the **angular gyrus**—are responsible for different aspects of language. [Review Figure 47.16](#), [WEB ACTIVITY 47.2](#)
- Some learning and memory processes have been localized to specific brain areas. Long-lasting changes in synaptic properties referred to as **long-term potentiation (LTP)** and **long-term depression (LDP)** may be involved in learning and memory.
- Complex memories can be elicited by stimulating small regions of association cortex. Damage to the hippocampus can destroy the ability to form long-term **declarative memory** but not **procedural memory**.
- A sense of the physiological state of the body may be created in the insular cortex from visceral afferent information. Evolution of this integrative function in higher primates and humans could be the basis for conscious experience.

[SEE WEB ACTIVITY 47.3 for a concept review of this chapter.](#)

SELF-QUIZ

- Which of the following describes the route of sensory information from the foot to the brain?
 - Ventral horn, spinal cord, medulla, cerebellum, midbrain, thalamus, parietal cortex
 - Dorsal horn, spinal cord, medulla, pons, midbrain, hypothalamus, frontal cortex
 - Dorsal horn, spinal cord, medulla, pons, midbrain, thalamus, parietal cortex
 - Ventral horn, spinal cord, pons, cerebellum, midbrain, thalamus, parietal cortex
 - Dorsal horn, spinal cord, medulla, pons, midbrain, thalamus, frontal cortex
- Which statement about the reticular system is *not* true?
 - Increased activity in the reticular system induces sleep.
 - The reticular system is located in the brainstem.
 - Damage to the reticular system in the midbrain can result in coma.
 - Information from the spinal cord is routed to different nuclei in the reticular system and to the forebrain.
 - There are groups of neurons called nuclei in the reticular system.
- Which statement about afferent and efferent pathways is *not* true?
 - Sympathetic and parasympathetic pathways carry only efferent information.
 - Visceral afferents carry information about physiological functions of which we are not consciously aware.
 - The voluntary division of the efferent portion of the peripheral nervous system executes conscious movements.
 - The cranial nerves and spinal nerves are part of the peripheral nervous system.
 - Afferent and efferent axons never travel in the same nerve.
- Which statement about the limbic system is *not* true?
 - Damage to one structure in the limbic system makes it impossible to form a fear memory.
 - The limbic system is involved in basic physiological drives, instincts, and emotions.
 - The limbic system consists of primitive forebrain structures.
 - In humans, the limbic system is the largest part of the brain.
 - In humans, a part of the limbic system is necessary for the transfer of short-term memory to long-term memory.
- Which of the following represents the largest portion of the human cerebral cortex?
 - The frontal lobes
 - The primary somatosensory cortex
 - The temporal cortex
 - The association cortex
 - The occipital cortex
- Which statement about the autonomic nervous system is *true*?
 - The sympathetic division is afferent, and the parasympathetic division is efferent.
 - The transmitter norepinephrine is always excitatory, and acetylcholine is always inhibitory.
 - Each pathway in the autonomic nervous system includes two neurons, and the neurotransmitter of the first neuron is acetylcholine.
 - The cell bodies of many sympathetic preganglionic neurons are in the brainstem.
 - The cell bodies of most parasympathetic postganglionic neurons are in or near the thoracic and lumbar spinal cord.
- Which statement about cells in the visual cortex is *not* true?
 - Many cortical cells receive inputs directly from single retinal ganglion cells.
 - Many cortical cells respond most strongly to bars of light falling at specific locations on the retina.
 - Some cortical cells respond most strongly to bars of light falling anywhere over large areas of the retina.
 - Some cortical cells receive input from both eyes.
 - Some cortical cells respond most strongly to an object when it is a certain distance from the eyes.
- Which of the following characterizes non-REM sleep?
 - Dreaming
 - Paralysis of skeletal muscles
 - EEG slow waves
 - Rapid and jerky eye movements
 - It makes up about 20 percent of total sleep time.
- Which conclusion was supported by experiments on split-brain patients?
 - Language abilities are localized mostly in the left cerebral hemisphere.
 - Language abilities require both Wernicke's area and Broca's area.
 - The ability to speak depends on Broca's area.
 - The ability to read depends on Wernicke's area.
 - The left hand is served by the left cerebral hemisphere.
- In the withdrawal reflex,
 - action potentials in a pain sensory neuron enter the spinal cord through the ventral root on the same side of the body.
 - the axon from a pain sensory neuron makes inhibitory synapses with motor neurons on the same side of the spinal cord and inhibitory synapses with motor neurons on the other side of the spinal cord.
 - coordinated escape reactions can be initiated before the brain registers the painful sensation.
 - axons from the pain sensory neuron make synapses with sympathetic preganglionic neurons in the spinal cord.
 - axons from motor neurons on the same side of the spinal cord that receives the input from the pain receptors cross the spinal cord to stimulate muscles on the other side of the body.

FOR DISCUSSION

1. A person receives a stab wound to the left side of his neck. Miraculously, blood vessels are spared. Afterward, however, the man's left pupil remains more constricted than his right pupil, and he drools out of the left side of his mouth. How can you explain these symptoms?
2. The stretch receptors in muscles are modified muscle cells, and they have their own motor neurons. What is the function of those motor neurons? In thinking about this question, remember that the function of the monosynaptic reflex is to adjust muscle tension to a change in load so that the position of the limb does not change.
3. A patient is unable to speak coherently. She can read and write and has no obvious loss of muscle function. Where would you expect to find an abnormality if you did brain scans of this patient?
4. How can you investigate how visual images falling on the retina are communicated to the brain? Start with the retina, and imagine how you would continue your investigation in visual areas of the brain.
5. We described the organization of the visual cortex as columns of cells that alternately receive input from the left and right eye. If a young kitten is allowed to see light out of only one eye for a day, more synapses are maintained in the cortical columns receiving input from that eye, while synapses decrease in the intervening columns. This redistribution of synapses does not occur, however, if the kitten is not allowed to sleep. What hypotheses could you propose on the basis of these results?

ADDITIONAL INVESTIGATION

The images in Figure 47.16 were made using technology that enables us to image regional activity in the brain. How would you use this imaging methodology to investigate a higher brain function that is of interest to you? First, formulate your hypothesis. Then design your investigation, keeping in mind that your subject

has to lie motionless in a large machine during the imaging. You will have to plan how you will deliver the appropriate stimulus to elicit the response or activity you are interested in. Also, describe what controls you will use to draw clear conclusions about the stimulus-response relationships you expect to observe.

Champion jumpers

The Olympic record for the women's long jump is 7.4 meters, set in 1988 by Jackie Joyner-Kersey. Another world-record long jump that still stands was set two years earlier by Rosie the Ribeter, who jumped 6.5 meters. Rosie was a frog competing in the Calaveras County Jumping Frog Contest. In some ways, Rosie's jump is more impressive: while Jackie's jump was about 5 times her body length (i.e., her height), Rosie's was about 20 times her body length.

Both jumps were powered by skeletal muscle. Muscle tissue responds to commands from the nervous system. The cellular mechanisms of muscle contraction are essentially the same in the frog and the human, so why is the frog's jump so much more impressive? The answer involves the concept of *leverage*, which depends on the muscles and skeletal elements working together.

Both frog and human jumping muscles pull on bones that are connected at joints to make levers. A lever makes it possible for the same force to move a large mass a small distance or a small mass a large distance. The ratio of a frog's leg length to its body mass is simply greater than that in a human. Thus the frog's legs are better at moving a small mass a long distance than are the human's legs.

Let's add a flea to our interspecies competition. The flea can jump more than 200 times its body length. This incredible performance is not due to feats of leverage, because no muscle can contract fast enough to explain the take-off velocity of the flea. A different mechanism evolved in the flea—a kind of slingshot action. At the base of the flea's jumping legs is an elastic material that is compressed by muscles while the flea is resting. When a trigger mechanism is released, the elastic material recoils and “fires” the flea into the air.

In a contest of jumping endurance, the uncontested champion would be the kangaroo. As a human runs faster, the number of strides and the energy expended per minute increase rapidly. Neither is true for the kangaroo. When moving at speeds from about 5 to 25 kilometers per hour, the kangaroo takes the same number of strides per minute and its metabolic rate does not increase. Why is this?

In kangaroos, as in frogs and humans, the muscles used to jump are attached to bones by tendons. Like the material at the base of the flea's

A Champion Jumper Jackie Joyner-Kersey set an Olympic record for the women's long jump at the Seoul Olympics in 1988.

Champion Jumpers Relative to their size, many animals have more impressive jumping skills than humans. This leopard frog (*Rana pipiens*) can leap distances up to 20 times its body length.

legs, tendons can be elastic. The kangaroo's tendons stretch when it lands, and their recoil helps power the next jump—similar to the action of a pogo stick. To move faster, the kangaroo simply increases the length of its stride, thereby increasing both the stretch on its tendons each time it lands and the magnitude of the recoil at the initiation of each jump.

As discussed in Chapter 31, the ability to move is one of the things that distinguishes animals from the other multicellular organisms. It is our muscles and skeleton—the *musculoskeletal system*—that allow us to move.

IN THIS CHAPTER we will describe muscle structure and the molecular mechanisms of contraction. We will discuss the properties that enable different types of muscles to perform different kinds of tasks. To generate specific kinds of movement, muscles must have something to pull on; thus we will describe skeletal systems and their roles in generating movement.

CHAPTER OUTLINE

- 48.1** How Do Muscles Contract?
- 48.2** What Determines Muscle Performance?
- 48.3** How Do Skeletal Systems and Muscles Work Together?

48.1 How Do Muscles Contract?

Most behavior and many physiological actions, such as beating of the heart and moving of food through the digestive tract, depend on muscle contraction. Wherever tissues contract, muscle cells are responsible. As introduced in Section 40.1 and shown in Figure 40.4, there are three types of vertebrate muscle:

- **Skeletal muscle** is responsible for all voluntary movements, such as running or playing a piano. It is also involved in some involuntary actions, such as breathing, shivering and maintaining posture.
- **Cardiac muscle** is responsible for the beating action of the heart.
- **Smooth muscle** creates the movement in many hollow internal organs, such as the gut, bladder, and blood vessels, and is under the control of the autonomic (involuntary) nervous system.

All three muscle types use the same *sliding filament contractile mechanism*, and we begin our study of musculoskeletal movement by describing its underlying molecular mechanisms. We will use vertebrate skeletal muscle as our primary example. Later we will discuss the differences in cardiac and smooth muscle that adapt them to their particular functions.

Sliding filaments cause skeletal muscle to contract

Skeletal muscle is also called *striated muscle* because of its striped appearance (see Figure 40.4A). Skeletal muscle cells, called **muscle fibers**, are large and have many nuclei. These multinucleate cells form in development through the fusion of many individual embryonic muscle cells called *myoblasts*. A specific muscle such as your biceps (which bends your arm) is composed of hundreds or thousands of muscle fibers bundled together by connective tissue (**Figure 48.1**).

Muscle contraction is due to the interaction between the contractile proteins **actin** and **myosin**. Within muscle cells, actin and myosin molecules are organized into filaments consisting of many molecules. Actin filaments are also called *thin filaments*, and myosin filaments are *thick filaments*. The two kinds of filaments lie parallel to each other. When muscle contraction is triggered, the actin and myosin filaments slide past each other in a telescoping fashion.

What is the relationship between a skeletal muscle fiber and the actin and myosin filaments responsible for its contraction? Each muscle fiber is packed with **myofibrils**—bundles of thin actin and thick myosin filaments arranged in orderly fashion. In most regions of the myofibril, each thick myosin filament is surrounded by six thin actin filaments, and each thin actin filament sits within a triangle of three thick myosin filaments.

48.1 The Structure of Skeletal Muscle

A skeletal muscle is made up of bundles of muscle fibers. Each muscle fiber is a multinucleate cell containing numerous myofibrils, which are highly ordered assemblages of thick myosin and thin actin filaments. The arrangement of the actin and myosin filaments gives skeletal muscle fibers their characteristic striated appearance.

A longitudinal view of a myofibril reveals why skeletal muscle appears striated. The myofibril consists of repeating units called **sarcomeres**. Each sarcomere is made of overlapping filaments of actin and myosin, which create a distinct banding pattern (see Figure 48.1). Before the molecular nature of the muscle banding pattern was known, the bands were given names that are still used today. Each sarcomere is bounded by *Z lines*, which anchor the thin actin filaments. Centered in the sarcomere is the *A band*, which contains all the myosin filaments. The *H zone* and the *I band*, which appear light, are regions where actin and myosin filaments do not overlap in the relaxed muscle. The dark stripe within the H zone is called the *M band*; it contains proteins that help hold the myosin filaments in their regular arrangement.

Where there are only actin filaments the myofibril appears light; where there are both actin and myosin filaments the myofibril appears dark.

yourBioPortal.com

GO TO Web Activity 48.1 • The Structure of a Sarcomere

48.2 Sliding Filaments

The banding pattern of the sarcomere changes as it shortens. Observations of electron micrographs such as those on the right led to the sliding filament hypothesis of muscle contraction.

The bundles of myosin filaments are held in a centered position within the sarcomere by a protein called **titin**. Titin is the largest protein in the body; it runs the full length of the sarcomere from Z line to Z line. Each titin molecule runs right through a myosin bundle. Between the ends of the myosin bundles and the Z lines, titin molecules are very stretchable, like bungee cords. In a relaxed skeletal muscle, resistance to stretch is mostly due to the elasticity of the titin molecules.

As the muscle contracts, the sarcomeres shorten and the band pattern changes. The H zone and the I band become much narrower, and the Z lines move toward the A band as if the actin filaments were sliding into the H zone, the region occupied by the myosin filaments (**Figure 48.2**). In the mid 1950s, this observation independently led two teams of British biologists to propose the **sliding filament model** of muscle contraction.

It is not uncommon in science for critical breakthroughs to be made simultaneously in different laboratories, but in this case the coincidences are remarkable. The leaders of the two teams were named Hugh Huxley and Andrew Huxley—but they were not related. Working in separate Cambridge University labs, the two groups proposed the sliding filament model at the same time, and both papers were published in the same issue of the journal *Nature*.

Actin–myosin interactions cause filaments to slide

To understand how the sliding filament model explains muscle contraction, we must first examine the structures of actin and myosin (**Figure 48.3**). A myosin molecule consists of two long polypeptide chains coiled together, each ending in a large globular head. A myosin filament is made up of many myosin molecules arranged in parallel, with their heads projecting sideways at each end of the filament.

An actin filament consists of actin monomers polymerized into a long molecule that looks like two strands of pearls twisted together. Twisting around the actin chains is another protein, *tropomyosin*, and attached to tropomyosin at intervals are molecules of *troponin*. We'll discuss the latter two proteins in the next section.

The myosin heads can bind specific sites on actin, forming cross-bridges between the myosin and the actin filaments. Moreover, when a myosin head binds to an actin filament, the head's conformation changes, and it bends and exerts a tiny force that causes the actin filament to move 5 to 10 nanometers relative to the myosin filament. The myosin heads also have ATPase ac-

48.3 Actin and Myosin Filaments Overlap to Form Myofibrils

Myosin filaments are bundles of molecules with globular heads and polypeptide tails; the protein titin holds these filaments centered within the sarcomeres. Actin filaments consist of two chains of actin monomers twisted together. They are wrapped by chains of the polypeptide tropomyosin and are studded at intervals with another protein, troponin.

GO TO Animated Tutorial 48.1 • Molecular Mechanisms of Muscle Contraction

tivity; when they are bound to actin, they can bind and hydrolyze ATP. The energy released when this happens changes the conformation of the myosin head, causing it to release the actin and return to its extended position, from which it can bind to actin again.

Together, these details explain the cycle of events that cause the actin and myosin filaments to slide past each other and shorten the sarcomere. They also explain *rigor mortis*—the stiffening of muscles soon after death. ATP is needed to break the actin–myosin bonds, so when ATP production ceases with death, the actin–myosin bonds cannot be broken and the muscles stiffen. Eventually, however, the proteins begin to lose their integrity, and the muscles soften. The timing of these events helps a medical examiner estimate the time of death.

We have been discussing the cycle of contraction in terms of a single myosin head. Remember that each myosin filament has many myosin heads at both ends and is surrounded by six actin filaments; thus the contraction of the sarcomere involves a great many cycles of interaction between actin and myosin molecules. That is why when a single myosin head breaks its contact with actin, the actin filaments do not slip backward.

Actin–myosin interactions are controlled by calcium ions

Like neurons, muscle cells are *excitable*—that is, their plasma membranes can generate and conduct action potentials. In skeletal muscle fibers, action potentials are initiated by motor neurons arriving at a *neuromuscular junction*. The axon terminals of motor neurons are generally highly branched and form synapses with hundreds of muscle fibers (Figure 48.4). A motor neuron and all of the fibers with which forms synapses constitute a **motor unit**. The fibers contract simultaneously when its motor neuron fires. A muscle can consist of many motor units. Thus, there are two ways to increase a muscle's strength of contraction: increase the firing rate of an individual motor neuron, or recruit more motor neurons.

As described in Section 45.3, when an action potential arrives at a neuromuscular junction, the neurotransmitter acetylcholine is released from the motor neuron terminals, diffuses across the synaptic cleft, binds to receptors in the postsynaptic membrane, and causes ion channels in the motor end plate to open (see Figures 45.13 and 45.14). Most of the ions that flow through these channels are Na^+ , and therefore the motor end plate is depolarized. The depolarization spreads to the surrounding plasma membrane of the muscle fiber,

48.4 The Neuromuscular Junction Axons branching from a single motor neuron end in terminals that innervate multiple skeletal muscle fibers.

which contains voltage-gated sodium channels. When threshold is reached, the plasma membrane fires an action potential that is conducted rapidly to all points on the surface of the muscle fiber.

An action potential in a muscle fiber also travels deep within the cell. The plasma membrane is continuous with a distribution system of tubules that descend into the muscle fiber cytoplasm (also called the **sarcoplasm**). The action potential that spreads over the plasma membrane also spreads through this system of transverse tubules, or **T tubules** (Figure 48.5).

The T tubules come very close to the endoplasmic reticulum (ER) of the muscle cell. In muscle cells, the ER is called the **sar-**

48.5 T Tubules Spread Action Potentials into the Fiber

An action potential at the neuromuscular junction spreads throughout the muscle fiber via a network of T tubules, triggering the release of Ca^{2+} from the sarcoplasmic reticulum.

yourBioPortal.com

GO TO Web Activity 48.2 • The Neuromuscular Junction

saroplasmic reticulum, and it is a closed compartment surrounding every myofibril. Calcium pumps in the sarcoplasmic reticulum take up Ca^{2+} ions from the sarcoplasm. Therefore, when the muscle fiber is at rest, there is a higher concentration of Ca^{2+} in the sarcoplasmic reticulum and a lower concentration in the sarcoplasm.

Spanning the space between the membranes of the T tubules and the membranes of the sarcoplasmic reticulum are two proteins. One protein, the *dihydropyridine (DHP) receptor*, is located in the T tubule membrane; it is voltage-sensitive and changes its conformation when an action potential reaches it. The other protein, the *ryanodine receptor*, is located in the sarcoplasmic reticulum membrane; it is a Ca^{2+} channel. These two proteins are physically connected. When the DHP receptor is activated by an action potential, it changes conformation, causing the ryanodine receptor to allow Ca^{2+} to leave the sarcoplasmic reticulum. Ca^{2+} ions diffuse into the sarcoplasm surrounding the actin and myosin filaments and trigger the interaction of actin and myosin and the sliding of the filaments. How do the Ca^{2+} ions do this?

An actin filament, as we have seen, is a helical arrangement of actin monomers. Twisted around the actin filament are two strands of the protein **tropomyosin** (Figure 48.6; see also Figure 48.3). At regular intervals, the filament also includes a globular protein, **troponin**. The troponin molecule has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

When the muscle is at rest, the tropomyosin strands are positioned so that they block the sites on the actin filament where myosin heads can bind. When Ca^{2+} is released into the sarcoplasm, it binds to troponin, changing its conformation. Because the troponin is bound to the tropomyosin, this conformational change twists the tropomyosin enough to expose the actin–myosin binding sites. Thus the cycle of making and breaking actin–myosin bonds is initiated, the filaments are pulled past each other, and the muscle fiber contracts. When the calcium pumps remove the Ca^{2+} ions from the sarcoplasm, the conformation of the tropomyosin returns to the state in which it blocks the binding of myosin heads to actin, and the muscle fiber returns to its resting condition. Figure 48.6 summarizes this cycle.

48.6 Release of Ca^{2+} from the Sarcoplasmic Reticulum Triggers Muscle Contraction When Ca^{2+} binds to troponin, it exposes myosin-binding sites on the actin. As long as binding sites and ATP are available, the cycle of actin and myosin interactions continues and the filaments slide past each other.

Cardiac muscle is similar to and different from skeletal muscle

Like skeletal muscle, cardiac muscle appears striated because of the regular arrangement of actin and myosin filaments into sarcomeres (**Figure 48.7**). The difference between cardiac and skeletal muscle is that cardiac muscle cells are much smaller and have only one nucleus each (*uninucleate*). Cardiac muscle cells branch, and the branches of adjoining cells interdigitate into a meshwork that is resistant to tearing. As a result, the heart walls can withstand high pressures while pumping blood, without the danger of developing leaks. Adding to the strength of cardiac muscle are *intercalated discs* that provide strong mechanical adhesions between adjacent cells. Gap junctions—protein structures that allow cytoplasmic continuity between cells—in the intercalated discs offer low-resistance pathways for ionic currents to flow between cells (see Figure 7.21A and Section 45.3). Therefore, cardiac muscle cells are electrically coupled. An action potential initiated at one point in the heart spreads rapidly through a large mass of cardiac muscle.

Certain cardiac muscle cells are specialized for generating and conducting electrical signals. These *pacemaker* and *conducting cells* have a low density of actin and myosin filaments, but they initiate and coordinate the rhythmic contractions of the heart. (The molecular basis for this pacemaking function is covered in Section 50.3.) Pacemaker cells make the vertebrate heartbeat *myogenic*, meaning it is generated by the heart muscle itself. A heart removed from a vertebrate can continue to beat with no input from the nervous system; although input from the autonomic nervous system modifies the *rate* of the pacemaker cells, it is not essential for their continued rhythmic function.

The mechanism of excitation–contraction coupling in cardiac muscle cells is different from that in skeletal muscle cells. The T tubules are larger, and the voltage-sensitive DHP proteins in the T tubules are Ca^{2+} channels. These T tubule proteins are not

48.7 Cardiac Muscle Cells Form a Strong Meshwork Cardiac muscle cells branch and interdigitate, forming a tear-resistant mesh that can withstand the pressure of blood pumping through the heart.

physically connected with the ryanodine receptors in the sarcoplasmic reticulum. Instead, the ryanodine receptors are ion-gated Ca^{2+} channels that are sensitive to Ca^{2+} . When an action potential spreads down the T tubules, it causes the voltage-gated channels to open, allowing extracellular Ca^{2+} to flow into the sarcoplasm. This slight rise in sarcoplasmic Ca^{2+} concentration opens the Ca^{2+} channels in the sarcoplasmic reticulum, which in turn causes a huge rise in sarcoplasmic Ca^{2+} concentration, resulting in fiber contraction. This mechanism is called *Ca^{2+} -induced Ca^{2+} release*.

Smooth muscle causes slow contractions of many internal organs

Smooth muscle provides the contractile force for most of our internal organs, which are under the control of the autonomic nervous system. Smooth muscle moves food through the digestive tract, controls the flow of blood through blood vessels, and empties the urinary bladder. Structurally, smooth muscle cells are the simplest muscle cells. They are smaller than skeletal muscle cells, usually long and spindle-shaped, and each has a single nucleus. They are “smooth” because the actin and myosin filaments are not as regularly arranged as they are in skeletal and cardiac muscle, and so do not produce the striated appearance.

Some smooth muscle tissue, such as that from the wall of the digestive tract, has interesting properties. The cells are arranged in sheets, and individual cells in a sheet are in electrical contact with one another through gap junctions, as they are in cardiac muscle. As a result, an action potential generated in the membrane of one smooth muscle cell can spread to all the cells in the sheet of tissue. Thus the cells in the sheet contract in a coordinated fashion.

The plasma membranes of smooth muscle cells are sensitive to stretch, with important consequences. If the wall of the digestive tract is stretched in one location (as by a mouthful of food passing down the esophagus to the stomach), the membranes of the stretched cells depolarize, reach threshold, and fire action potentials, which cause the cells to contract. Thus, smooth muscle contracts after being stretched, and the harder it is stretched, the stronger it contracts. This behavior of smooth muscle is important for moving food through the gut.

The walls of blood vessels are mostly smooth muscle. This is especially true on the arterial side where the blood is under higher pressure. The muscle tone in these vessels is responsive to changes in blood pressure and to both chemical and neural influences, as we discuss in Chapter 50. Changes in vascular smooth muscle tone are responsible for controlling the distribution of blood in the body.

The neural influences on smooth muscle come from the two divisions of the autonomic nervous system. The neurotransmitters of the sympathetic and parasympathetic postganglionic cells alter the membrane potential of smooth muscle cells. For example, in the digestive tract, acetylcholine causes smooth muscle cells to depolarize, making them more likely to fire action potentials and contract. Antagonistically, norepinephrine causes these muscle cells to hyperpolarize and thus be less likely to fire action potentials and contract (**Figure 48.8**). In contrast, norep-

INVESTIGATING LIFE

48.8 Neurotransmitters Alter the Membrane Potential of Smooth Muscle Cells

Earlier experiments showed that stretching the smooth muscles of the gut (as in the stretch applied by a full stomach) depolarizes the membranes, causing action potentials that activate the contractile mechanism. This follow-up experiment showed that the parasympathetic neurotransmitter acetylcholine and the sympathetic neurotransmitter norepinephrine act antagonistically to alter the membrane potential of smooth muscle.

HYPOTHESIS Stimulation from neurotransmitters of the autonomic nervous system induce contractions in the smooth muscles of the gut.

METHOD

RESULTS

CONCLUSION ANS neurotransmitters can alter membrane resting potentials and affect the rate at which smooth muscle cells fire action potentials, thus controlling smooth muscle contraction.

inephrine acting through G protein-coupled receptors causes the smooth muscle in arteries serving the gut to contract. Remember that the action of the neurotransmitters depends on the receptors in the target tissues. Sympathetic activity is high in a fight-or-flight situation; in an emergency you don't need to digest your lunch, but you do need to send blood to the tissues critical for survival.

Although smooth muscle cell contraction is not controlled by the troponin–tropomyosin mechanism, calcium still plays a critical role. A Ca^{2+} influx into the sarcoplasm of a smooth muscle cell can be stimulated by action potentials, hormones, or stretching. The Ca^{2+} that enters the sarcoplasm combines with a protein called *calmodulin*. The calmodulin– Ca^{2+} complex activates an enzyme called myosin kinase, which can phosphory-

48.9 The Role of Ca^{2+} in Smooth Muscle

Contraction When a smooth muscle cell is stimulated by neurotransmitter, Ca^{2+} enters the sarcoplasm and binds to calmodulin, which in turn activates an enzyme that phosphorylates the myosin heads, causing them to bind to actin. As long as the myosin remains phosphorylated, actin and myosin go through cycles of binding and release. Thus in smooth muscle, the Ca^{2+} -mediated change is on myosin, whereas in skeletal and cardiac muscle it is on the actin-tropomyosin filament.

The T tubule system causes a minimum unit of contraction, called a **twitch**. A twitch can be measured in terms of the *tension*, or force, it generates (Figure 48.10A). A single action potential stimulates a single twitch, but the ultimate force generated by an action potential can vary enormously depending on how many muscle fibers are in the motor unit it innervates. The level of tension an entire muscle generates depends on two factors: the number of motor units activated, and the frequency at which the motor units fire.

In muscles responsible for fine movements, such as those of the fingers, a motor neuron may innervate only one or a few muscle fibers, but in a muscle that produces large forces, such as the biceps, a motor neuron innervates a large number of muscle fibers.

At the level of a muscle fiber, a single action potential stimulates a single twitch. If action potentials reaching the muscle fiber are adequately separated in time, each twitch is a discrete, all-or-none phenomenon. If action potentials are fired more rapidly, however, new twitches are triggered before the myofibrils have a chance to return to their resting condition. As a result, the twitches sum, and the tension generated by the fiber increases and becomes more sustained. Thus an individual muscle fiber can show a graded response to increased levels of stimulation by its motor neuron.

Twitches sum at high levels of stimulation because the calcium pumps in the sarcoplasmic reticulum are not able to clear the Ca^{2+} ions from the sarcoplasm between action potentials.

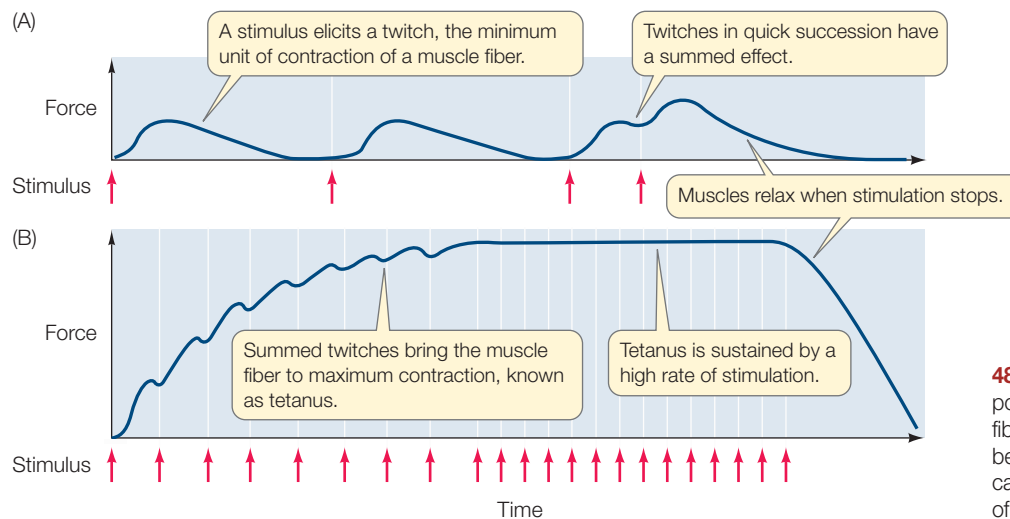

late myosin heads. When the myosin heads in smooth muscle are phosphorylated, they undergo cycles of binding and releasing actin, causing muscle contraction. As Ca^{2+} is removed from the sarcoplasm, it dissociates from calmodulin, and the activity of myosin kinase falls. An additional enzyme, myosin phosphatase, dephosphorylates the myosin to help reduce actin-myosin interactions (Figure 48.9).

GO TO Animated Tutorial 48.2 • Smooth Muscle Action

Single skeletal muscle twitches are summed into graded contractions

In skeletal muscle, the arrival of an action potential at a neuromuscular junction causes an action potential in a muscle fiber. The spread of that action potential through the muscle fiber's

48.10 Twitches and Tetanus

(A) Action potentials from a motor neuron cause a muscle fiber to twitch. Twiches in quick succession can be summed. (B) Summation of many twiches can bring the muscle fiber to the maximum level of contraction, known as tetanus.

Eventually a stimulation frequency can be reached that results in continuous presence of Ca^{2+} in the sarcoplasm at high enough levels to cause continuous activation of the contractile machinery—a condition known as **tetanus** (Figure 48.10B). (Do not confuse this condition with the disease called tetanus, which is caused by a bacterial toxin and is characterized by spastic contractions of skeletal muscles.)

How long a muscle fiber can maintain a tetanic contraction depends on its supply of ATP. Eventually the fiber will become fatigued. It may seem paradoxical that the *lack* of ATP causes fatigue, since the action of ATP is to break actin–myosin bonds. But remember that the energy released from the hydrolysis of ATP “re-cocks” the myosin heads, allowing them to cycle through another power stroke. When a muscle is contracting against a load, the cycle of making and breaking actin–myosin bonds must continue, to prevent the load from stretching the muscle. The situation is like rowing a boat upstream: you cannot maintain your position relative to the stream bank by just holding the oars out against the current; you have to keep rowing. Likewise, actin–myosin bonds have to keep cycling to maintain tension in the muscle.

Many muscles of the body maintain a low level of tension even when the body is at rest. For example, the muscles of the neck, trunk, and limbs that maintain our posture against the pull of gravity are always working, even when we are standing or sitting still. *Muscle tone* comes from the activity of a small but changing number of motor units in a muscle; at any one time, some of the muscle’s fibers are contracting and others are relaxed. The nervous system is constantly readjusting muscle tone.

48.1 RECAP

The contractile ability of muscle derives from interactions between actin and myosin filaments. The three types of muscle are skeletal, cardiac, and smooth. Contraction in all three depends on control of Ca^{2+} in the sarcoplasm. Tropomyosin and troponin are controlling elements in skeletal and cardiac muscle. Calmodulin is the controlling element in smooth muscle.

- Explain how the cellular and subcellular structure of skeletal muscle relate to the sliding filament theory of muscle contraction. **See pp. 1007–1009 and Figures 48.1, 48.2, and 48.3**
- What is the role of Ca^{2+} in the contractile mechanism of skeletal, cardiac, and smooth muscle? **See pp. 1010–1011 and Figures 48.5 and 48.6**
- What role does ATP play in the actin and myosin interactions that produce contraction? **See Figure 48.6**

Now that we understand how muscles generate force, we can look at what determines the characteristics of a muscle, and how individual muscles can change their characteristics with regular use and conditioning.

48.2 What Determines Muscle Performance?

The functions that different muscles perform place different demands on them. Some muscles, such as postural muscles, must sustain a load continuously over long periods of time. Other muscles, such as those that control your fingers, generally do not have to sustain long contractions, but they must be able to contract quickly. And what is “quick” for humans doesn’t begin to compare with insect flight muscles that can contract as fast as 1,000 times per second. How are muscles adapted to specific functions and demands?

Muscle fiber types determine endurance and strength

Not all skeletal muscle fibers are alike, and a single muscle often contains more than one type of fiber. The two major types of skeletal muscle fibers express different genes for their myosin molecules, and these myosin variants have different rates of ATPase activity. Those with high ATPase activity can recycle their actin–myosin cross-bridges rapidly and are therefore called fast-twitch fibers. Slow-twitch fibers have lower ATPase activity; they develop tension more slowly but can maintain it longer.

Slow-twitch fibers are also called *oxidative* or *red muscle* because they contain the oxygen-binding protein *myoglobin*, have many mitochondria, and are well supplied with blood vessels. These characteristics both increase the fibers’ capacity for oxidative metabolism and result in their red appearance. The maximum tension a slow-twitch fiber produces is low and develops slowly but is highly resistant to fatigue. Slow-twitch fibers have substantial reserves of fuel (glycogen and fat), so they can maintain steady, prolonged production of ATP as long as oxygen is available. Muscles with high proportions of slow-twitch fibers are good for long-term *aerobic* work (that is, work that requires oxygen). Long-distance runners, swimmers, cyclists, and other athletes whose activities require endurance have leg and arm muscles consisting mostly of slow-twitch fibers (Figure 48.11).

Some **fast-twitch fibers** are also called *glycolytic* or *white muscle* because, compared with slow-twitch fibers, they have few mitochondria, little or no myoglobin, and fewer blood vessels; thus they look pale. Fast-twitch glycolytic fibers can develop maximum tension more rapidly than slow-twitch fibers can, and that maximum tension is greater. However, fast-twitch fibers fatigue rapidly. The myosin of these fibers puts the energy of ATP to work very rapidly, but the fibers cannot replenish ATP quickly enough to sustain contraction for a long time. Fast-twitch fibers are especially good for short-term work that requires maximum strength. Weight lifters and sprinters have leg and arm muscles with high proportions of fast-twitch fibers.

The types of fibers that make up a muscle influence the performance properties of that muscle. A sprinter benefits from muscles that generate maximum force rapidly, but they do not need to sustain a particular load for a long time. By contrast, a marathon runner benefits from muscles with maximum endurance.

(A) Cross sections of leg muscles

(B)

48.11 Slow- and Fast-Twitch Muscle Fibers The skeletal muscles in the micrographs were stained with a reagent that shows slow-twitch fibers as dark and fast-twitch muscle as light. Athletes in different sports have different distributions of muscle fiber types.

What can you do to optimize your performance in a particular activity? To a limited extent, you can alter the properties of your muscle fibers through training. There are fast-twitch fibers that are somewhat oxidative and therefore intermediate in their properties between slow-twitch and fast glycolytic fibers. These intermediate fibers can become more oxidative with endurance training and more glycolytic with strength training. However, the most important determinant of your muscle fiber types is your genetic heritage. There is some truth to the statement that champions are born, not made. A person born with a high proportion of fast-twitch fibers is unlikely to become a champion marathon runner, and one born with a high proportion of slow-twitch fibers is unlikely to become a champion sprinter.

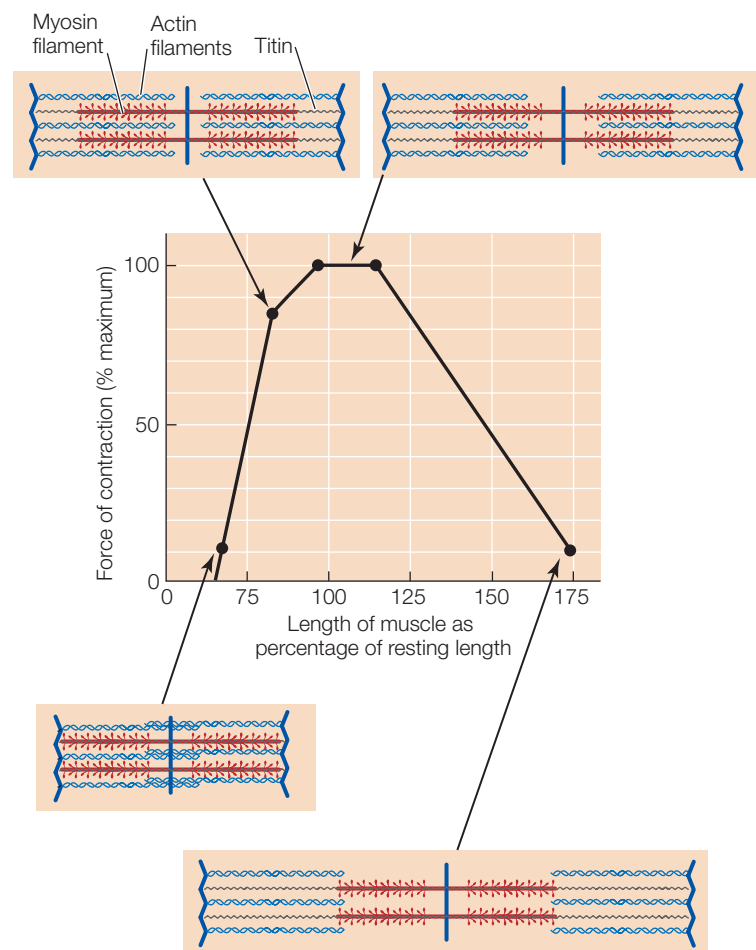

A muscle has an optimal length for generating maximum tension

If you have ever done a pull-up, you know that two parts of this exercise are especially difficult. When you are hanging from the bar with your arms fully extended, it is hard to get

the pull-up started; and when your chin has just about reached the bar, pulling yourself up the last small distance is difficult. Why is this? Part of the explanation comes from the lever properties of the muscle–joint interaction that we discuss in the next section, and part comes from the structure of the sarcomere.

When a muscle is stretched and the sarcomeres are lengthened, there is less overlap between the actin and myosin filaments; therefore, fewer cross-bridges can form, and less force can be produced. In fact, if the sarcomeres are stretched too much, actin and myosin do not overlap and no force can be produced. How would a muscle recover from such a difficult situation? The bungee cord–like titin molecules create enough elastic recoil to pull the actin and myosin fibrils back into an overlapping arrangement.

When the muscle is fully contracted, the actin and myosin filaments overlap so much that the myosin bundles are pressed up against the Z lines. Because they have no place to go, additional shortening is difficult. You can see the relationship between the length of a muscle fiber and its ability to develop tension in **Figure 48.12**.

48.12 Force and Length The amount of force a sarcomere can generate depends on its resting length. When a muscle is stretched, the sarcomeres lengthen, there is less overlap between the actin and myosin filaments, and less force is produced. Overstretched sarcomeres produce no force because there is no overlap between the actin and myosin.

Exercise increases muscle strength and endurance

Different types of exercise produce different physical conditioning responses. In general, anaerobic activities, such as weight lifting, increase strength, and aerobic activities, such as jogging, increase endurance. Strength is the maximum force that a muscle can exert, and endurance is work capacity or how long a given workload can be sustained. What are the physiological bases for these differences?

Strength is a function of the cross-sectional area of muscles: the more actin and myosin filaments in a muscle fiber, and the more muscle fibers in a muscle, the more tension it can produce. When athletes undertake strength training, they use weights or exercises such as pull-ups to repeatedly contract specific muscles under heavy loads. Repetitions are usually done until the muscle is completely fatigued. Such stress on a muscle does minor tissue damage—hence the soreness the day after a hard workout—but it also induces the formation of new actin and myosin filaments in existing muscle fibers. The muscle fibers, and hence the muscles, get bigger and stronger. In extreme cases, and after serious muscle damage, new muscle fibers can also be produced from stem cells called *satellite cells* in the muscle. In general, however, the major effect of strength training is to produce bigger, rather than more, muscle fibers.

Aerobic exercise has a completely different effect on muscles: it enhances their oxidative capacity. This effect comes from increases in the number of mitochondria, in enzymes involved in energy use, and in the density of capillaries that deliver oxygen to the muscle. Myoglobin also increases in skeletal muscle cells. **Myoglobin** is an oxygen-binding protein similar to hemoglobin in red blood cells. However, myoglobin has a higher affinity for oxygen than does hemoglobin. Therefore, myoglobin accepts oxygen from the blood, facilitates the diffusion of oxygen throughout the muscle, and provides a store of oxygen for use when oxygen delivery by the blood is insufficient. By increasing the capacity of muscle to use oxygen to produce ATP, aerobic training increases the work load that muscles can sustain through time.

Muscle ATP supply limits performance

Muscles have three systems for supplying the ATP they need for contraction:

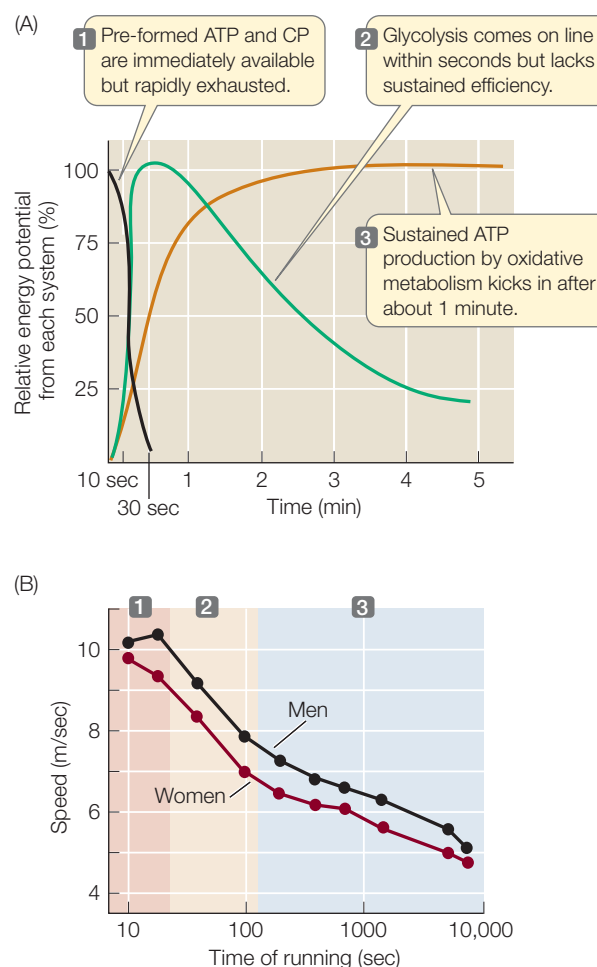

- The *immediate system* uses preformed ATP and creatine phosphate.
- The *glycolytic system* metabolizes carbohydrates to lactate and pyruvate.
- The *oxidative system* metabolizes carbohydrates or fats all the way to H_2O and CO_2 .

48.13 Supplying Fuel for High Performance (A) Muscles have three systems for obtaining the ATP they need for contraction during exertion such as running. (B) Looking at a plot of world-record times for running events of different durations, you can see that the performance of the athletes corresponds to the time courses of the three energy systems.

The capacity of these three systems and the rates at which they can produce ATP determine both work capacity and endurance (**Figure 48.13**).

ATP is present in muscles in very small amounts. However, muscle fibers also contain a storage compound called *creatine phosphate* (CP). This molecule stores energy in a phosphate bond, which it can transfer to ADP. The total energy available in all the muscles of your body in the form of ATP and CP—the immediate energy system—is only about 10 kilocalories. When at rest, you metabolize a kilocalorie of energy in less than a minute. Even though the energy available from ATP and CP is limited, it is available immediately, and it enables fast-twitch fibers to generate a lot of force quickly. During burst activity, the immediate system is exhausted in seconds.

The glycolytic system activates within a few seconds to replace the ATP depleted at the onset of muscle activity. The glycolytic enzymes are located in the cytoplasm of the muscle fiber, and therefore the ATP they generate is rapidly available to the myosin filaments. However, as noted in Chapter 9, glycolysis alone is an inefficient way to produce ATP, and it leads to the accumulation of lactic acid, which slows the process. Thus, the glycolytic system and the immediate system together can provide most of the energy for active muscles for less than a minute (see Figure 48.13).

Oxidative metabolism becomes fully active in about a minute, producing relatively huge amounts of ATP because it can completely metabolize carbohydrates and fats. However, it requires many reactions (see Chapter 9), and it takes place in the mitochondria, so O_2 and substrate must diffuse into the mitochondria, and the formed ATP must diffuse from the mitochondria to the myosin filaments in the muscle. These processes are not instantaneous, so the rate at which oxidative metabolism can make ATP available to do work is slower than the rate at which the other two systems can supply ATP.

The fuel supply available to the muscles influences how long someone can sustain a high level of aerobic exercise. From the circulating blood, muscle receives glucose and free fatty acids, which it can metabolize to generate ATP. At high levels of aerobic exercise, however, most of the fuel used by muscles to produce ATP comes from the reserve of glycogen stored in the muscle itself. Depletion of muscle glycogen results in fatigue.

The rate at which muscle glycogen is replenished depends on diet: it is high with a high-carbohydrate diet, low with a high-fat diet, and intermediate with a mixed diet. This fact is the basis for a practice called “carbo-loading.” For 3 to 5 days, athletes exercise at a level that depletes muscle glycogen. Then, 2 or 3 days before the event, they taper down their level of training and eat a diet rich in complex carbohydrates. The result can be glycogen supercompensation, in which the restoration of muscle glycogen stores “overshoots” and reaches above-normal levels.

Insect muscle has the greatest rate of cycling

Insect flight muscle can produce a wingbeat frequency of up to 1,000 cycles per second. Since neural action potentials last 1 to 3 milliseconds, that number of cycles per second would push the capacity of motor neurons, let alone the mechanism of cycling of the striated muscle contraction/relaxation. The wingbeat frequency of a hummingbird is less than 50 cycles per second, and that seems fast. How do insects do it?

The mechanism of excitation/contraction coupling is different in insect flight muscle. Vertebrate striated muscle and much of invertebrate striated muscle is called “synchronous” because the cycling of the contractile mechanism is linked to the firing of the motor neurons. This is not true of insect flight muscle, which is therefore called “asynchronous” muscle. The firing of action potentials in the insect flight motor neurons is not particularly fast, but it does cause depolarization of the muscle cell membrane, the spreading of an action potential throughout the membrane, and the release of Ca^{2+} from the sarcoplasmic reticulum. However, once the asynchronous muscle fiber is stimulated, its cycle of contraction/relaxation proceeds at its own characteristic frequency as long as the Ca^{2+} is available to bind to the troponin. The contraction of the muscle fiber deactivates the actin–myosin binding, which in turn permits a stretching of the muscle, which in turn activates the actin–myosin binding. Thus contractile cycling and the resulting wingbeat frequency are not tied to the firing rate of the flight motor neurons.

48.2 RECAP

Depending on the function a muscle serves, it may need to generate maximum force rapidly, sustain activity for a long period, or contract and relax at a very rapid rate. Properties of muscles can facilitate these types of activity.

- Describe the differences between slow-twitch and fast-twitch fibers. **See p. 1015 and Figure 48.11**
- How does exercise influence muscle strength and endurance? **See p. 1017**
- How do the different sources of ATP influence performance in different types of exercise? **See pp. 1017–1018 and Figure 48.13**
- Explain how insects can beat their wings 10 times faster than hummingbirds can. **See p. 1018**

Regardless of how much force a muscle can generate, how long it can sustain a work load, or how fast it can contract and relax, a muscle needs something to pull on; otherwise it would just be a lump of pulsating or quivering tissue. Let’s look now at how skeletal systems help generate movement.

48.3 How Do Skeletal Systems and Muscles Work Together?

Muscles can contract and exert force, or they can relax. To create significant movement, they must have something to pull on and something that stretches the muscle back to a longer position. In some cases, muscles pull on each other, as in the trunk of an elephant or the arms of an octopus. In most cases, however, **skeletal systems** are the rigid supports against which muscles pull to create directed movement. In this section, we examine the three types of skeletal systems: hydrostatic skeletons, exoskeletons, and endoskeletons.

A hydrostatic skeleton consists of fluid in a muscular cavity

Cnidarians, annelids, and other soft-bodied invertebrates have **hydrostatic skeletons** consisting of a volume of fluid enclosed in a body cavity surrounded by muscle (see Section 31.2). When muscles oriented in one direction contract, the fluid-filled body cavity bulges out in the opposite direction.

An earthworm uses its hydrostatic skeleton to crawl. The earthworm’s body cavity is divided into many separate segments, each of which contains a compartment filled with extracellular fluid. The body wall surrounding each segment has two muscle layers: a circular layer and a longitudinal layer. If the circular muscles in a segment contract, the compartment in that segment narrows and elongates. If the longitudinal muscles in a segment contract, the compartment shortens and bulges outward. Alternating contractions of the earthworm’s circular and longitudinal muscles create waves of narrowing and widening,

48.14 A Hydrostatic Skeleton Alternating waves of muscle contraction move the earthworm through the soil. The red dot enables you to follow the changes in one segment as the worm moves forward.

lengthening and shortening, that travel down the body. Bulging, shortened segments serve as anchors as long, narrow segments project forward and longitudinal contractions pull other segments forward. Bristles help the widest parts of the body to hold firm against the substratum (**Figure 48.14**).

Exoskeletons are rigid outer structures

An *exoskeleton* is a hardened, rigid outer surface to which muscles can be attached. Contractions of the muscles cause jointed segments of the exoskeleton to move relative to each other. The simplest example of an exoskeleton is the shell of a mollusk. Some marine mollusks, such as clams, have shells composed of protein strengthened by crystals of calcium carbonate (a rock-hard material). These shells can be massive, affording significant protection against predators. The shells of land mollusks (snails) generally lack the hard mineral component and are much lighter (see **Figure 32.15B,D**).

The most complex exoskeletons are found among the arthropods. An exoskeleton, or *cuticle*, covers all the outer surfaces of the arthropod's body and all its appendages. It is made up of plates secreted by a layer of cells just below the exoskeleton. The cuticle contains stiffening materials everywhere except at the joints, where flexibility must be retained. Muscles attached to the inner surfaces of the arthropod exoskeleton move its parts around the joints (see **Figure 32.4**).

A drawback of the rigid arthropod exoskeleton is that it cannot expand. Therefore, if the animal is to become larger, it must *molt*, shedding its exoskeleton and forming a new, larger one. A molting animal is vulnerable because the new exoskeleton takes time to harden. The animal's body is temporarily unprotected, and without a firm exoskeleton against which its mus-

cles can exert maximum tension, it is unable to move rapidly. Soft-shelled crabs, a gourmet delicacy, are crabs caught when they are molting.

Vertebrate endoskeletons consist of cartilage and bone

The **endoskeleton** of vertebrates is an internal scaffolding. Muscles are attached to it and pull against it. Endoskeletons are composed of rodlike, platelike, and tubelike bones connected to one another at a variety of joints that allow a wide range of movements. An advantage of endoskeletons over the exoskeletons of arthropods is that bones in the body can grow without the animal shedding its skeleton.

The human skeleton consists of 206 bones, some of which are shown in **Figure 48.15**. It can be divided into an *axial skeleton*, which includes the skull, vertebral column, sternum, and ribs; and an *appendicular skeleton*, which includes the pectoral girdle, pelvic girdle, and bones of the arms, legs, hands, and feet.

48.15 The Human Endoskeleton Cartilage and bone make up the internal skeleton of a human being.

The vertebrate endoskeleton consists of two kinds of connective tissue, *cartilage* and *bone*, which are produced by two kinds of connective tissue cells. *Cartilage cells* produce an extracellular matrix that is a tough, rubbery mixture of polysaccharides and proteins—mainly fibrous collagen. Collagen fibers run in all directions like reinforcing cords through the gel-like matrix and give it the well-known strength and resiliency of “gristle.” This matrix, called **cartilage**, is found in parts of the endoskeleton where both stiffness and resiliency are required, such as on the surfaces of joints where bones move against one another. Cartilage is also the supportive tissue in stiff but flexible structures such as the larynx (voice box), nose, and ear pinnae. Sharks and rays are called *cartilaginous fishes* because their skeletons are composed entirely of cartilage. In most other vertebrates, cartilage is the principal component of the embryonic skeleton, but during development most of it is gradually replaced by bone.

Bone also contains collagen fibers, but it gets its rigidity and hardness from an extracellular matrix of insoluble calcium phosphate crystals. Bone serves as a reservoir of calcium for the rest of the body and is in dynamic equilibrium with soluble calcium in the extracellular fluids of the body. This equilibrium is under the control of calcitonin and parathyroid hormone (see Figure 41.11). If too much calcium is taken from the skeleton, the bones are seriously weakened.

The living cells of bone—*osteoblasts*, *osteocytes*, and *osteoclasts*—are responsible for the constant dynamic remodeling of bone (**Figure 48.16**). **Osteoblasts** lay down new matrix material on bone surfaces. These cells gradually become surrounded by matrix and eventually become enclosed within the bone, at which point they cease laying down matrix but continue to exist within small lacunae (cavities) in the bone. In this state they are called **osteocytes**. Despite the vast amounts of matrix between them, osteocytes remain in contact with one another through long cellular extensions that run through tiny channels in the bone. Communication between osteocytes is important in controlling the activities of the cells that are laying down or removing bone.

The cells that resorb bone are the **osteoclasts**. They are derived from the same cell lineage that produces white blood cells. Osteoclasts erode bone, forming cavities and tunnels. Osteoblasts follow osteoclasts, depositing new bone. Thus the interplay of osteoblasts and osteoclasts constantly replaces and remodels the bones, allowing a bone to recover from damage and adjust to the forces placed on it.

How the activities of the bone cells are coordinated is not understood, but stress placed on bones somehow provides them with information. A remarkable finding in studies of astronauts who spent long periods in zero gravity was that their bones decalcified. Conversely, in athletes, certain bones thicken during training. Both thickening and thinning of bones are experienced by anyone who has had a leg in a cast for a long time: the bones of the uninjured leg carry the person’s weight and thicken while the bones of the inactive leg in the cast thin.

Because of the positive effects of physical stress on bone deposition, weight-bearing exercise is effective in preventing and treating the loss of bone density (and hence strength) known as *osteoporosis*. More than 25 million people in the United States

48.16 Bone Is Living Tissue Bones are constantly being remodeled by osteoblasts, which lay down bone, and osteoclasts, which resorb bone.

suffer from this debilitating condition. Although osteoporosis is most commonly a problem for postmenopausal women, it can occur in younger people as a result of malnutrition. For example, the condition known as *female athlete triad* includes eating disorders, cessation of menstrual cycling, and osteoporosis. These are interactive conditions in which the eating disorder and excessive training lead to malnutrition that can result in endocrine disruption and osteoporosis. Excessive training and malnutrition can lead to bone loss in males as well.

Bones develop from connective tissues

Bones are divided into two types on the basis of how they develop. **Membranous bone** forms on a scaffold of connective tissue membrane. **Cartilage bone** forms first as a cartilaginous structure resembling the future mature bone, then gradually hardens, or *ossifies*, to become bone. The outer bones of the skull are membranous bones; the bones of the limbs are cartilage bones.

Cartilage bones can grow throughout the ossification process. The long bones of the legs and arms, for example, ossify first at the centers and later at each end (**Figure 48.17**). Growth can continue until these areas of ossification join. The membranous bones forming the skull cap grow until their edges meet. The soft spot on the top of a baby’s head (the fontanelle) is the point at which the skull bones have not yet joined.

The structure of bone may be **compact** (solid and hard) or **cancellous** (having numerous internal cavities that make it appear spongy, although it is rigid). The architecture of a specific bone depends on its position and function, but most bones have both compact and cancellous regions. The shafts of the long bones of the limbs, for example, are cylinders of compact bone surrounding central cavities that contain the bone marrow, where the cellular elements of the blood are made. The ends of the long bones are cancellous (see Figure 48.17). Cancellous bone is lightweight because of its numerous cavities, but it is also strong because its internal meshwork constitutes a support system. It can withstand considerable forces of compression. The

48.17 The Growth of Long Bones In the long bones of human limbs, ossification occurs first at the centers and later at each end.

rigid, tubelike shaft of compact bone can withstand compression and bending forces. Architects and nature alike use hollow tubes as lightweight structural elements.

Most of the compact bone in mammals is called *Haversian bone* because it is composed of structural units called **Haversian systems** (Figure 48.18). Each Haversian system is a set of thin, concentric bony cylinders, between which are the osteocytes in their lacunae. Through the center of each Haversian system runs a narrow canal containing blood vessels and nerves. Adjacent Haversian systems are separated by boundaries called *glue lines*. Haversian bone is resistant to fracturing because cracks tend to stop at glue lines.

Bones that have a common joint can work as a lever

Muscles and bones work together around **joints**, where two or more bones come together. Different kinds of joints allow motion in different directions (Figure 48.19), but muscles can exert force in only one direction. Therefore, muscles create move-

48.18 Most Compact Bone Is Composed of Haversian Systems

A micrograph of a section of a long bone shows Haversian systems with their central canals. Glue lines separate Haversian systems.

48.19 Types of Joints The designs of joints are similar to mechanical counterparts and enable a variety of movements.

GO TO Web Activity 48.3 • Joints

48.20 Joints, Ligaments, and Tendons A side view of the knee shows the interactions of muscle, bone, cartilage, ligaments, and tendons at this crucial and vulnerable human joint.

ment around joints by working in antagonistic pairs: when one muscle contracts, the other relaxes. When both contract, the joint becomes rigid (which is important for maintaining posture, for example).

With respect to a particular joint, such as the knee, we refer to the muscle that bends, or flexes, the joint as the **flexor**, and the muscle that straightens, or extends, the joint as the **extensor**. The bones that meet at the joint are held together by **ligaments**, which are flexible bands of connective tissue. Other straps of connective tissue, called **tendons**, attach the muscles to the bones (**Figure 48.20**). In many kinds of joints, only the tendon spans the joint, sometimes moving over the surfaces of the bones like a rope over a pulley. The tendon of the quadriceps muscle traveling over the knee joint is what is tapped to elicit the knee-jerk reflex (see **Figure 47.3**).

Bones constitute a system of levers that are moved around joints by the muscles. A lever has an *effort arm* and a *load arm* that work around a *fulcrum* (pivot). The length ratio of the two arms determines whether a particular lever can exert a lot of force over a short distance or is better at translating force into large or fast movements. Compare the jaw and knee joints, for example (**Figure 48.21**). The effort arm of the jaw is long relative to the load arm, allowing the jaw to apply great force over a small distance. Think of the powerful jaws of carnivores that can easily crack bones. The effort arm of the lower leg, by contrast, is short relative to the load arm, so you can run fast, jump high, and deliver swift kicks.

48.21 Bones and Joints Work Like Systems of Levers A lever system can be designed for maximizing either force or speed.

48.3 RECAP

Muscles can only contract and relax; to achieve organized movement, they must pull against rigid structures—other muscles, hydrostatic skeletons, exoskeletons, or endoskeletons.

- How do the muscles and fluid-filled body cavity of an earthworm interact to enable the animal to crawl? **See pp. 1018–1019 and Figure 48.14**
- Describe the differences between membranous and cartilaginous bone and between compact and cancellous bone. **See p. 1020 and Figure 48.17**
- In terms of levers, explain how specific joints can produce maximum force versus maximum speed. **See pp. 1021–1022 and Figure 48.21**

CHAPTER SUMMARY

48.1 How Do Muscles Contract?

- **Skeletal muscle** consists of bundles of **muscle fibers**. Each skeletal muscle fiber is a large cell containing multiple nuclei.
- Skeletal muscles contain numerous **myofibrils**, which are bundles of **actin** and **myosin** filaments. The regular, overlapping arrangement of the actin and myosin filaments into **sarcomeres** gives skeletal muscle its striated appearance. **Review Figure 48.1, WEB ACTIVITY 48.1**
- The changes in the banding patterns of sarcomeres led to the **sliding filament model** of muscle contraction. **Review Figure 48.2, ANIMATED TUTORIAL 48.1**
- The molecular mechanism of muscle contraction involves the binding of the globular heads of myosin molecules to actin. Upon binding, the myosin head changes its conformation, causing the two filaments to move past each other (the sliding filament mechanism). Release of the myosin heads from actin and their return to their original conformation requires ATP. **Review Figures 48.3 and 48.6**
- All the fibers activated by a single motor neuron constitute a **motor unit**. Each nerve ending of the motor neuron forms a synapse with the muscle cell membrane. When neurotransmitter is released at the synapse, the muscle cell membrane is depolarized and action potentials are generated. Action potentials spread across the plasma membrane and through the **T tubules**, causing Ca^{2+} to be released from the **sarcoplasmic reticulum**. **Review Figure 48.5, WEB ACTIVITY 48.2**
- Ca^{2+} binds to **tropomyosin** and changes its conformation, pulling the **tropomyosin** strands away from the myosin-binding sites on the actin filament. The muscle fiber continues to contract until the Ca^{2+} is returned to the sarcoplasmic reticulum. **Review Figure 48.6**
- **Cardiac muscle** cells are striated, uninucleate, branching, and electrically connected by gap junctions, so that action potentials spread rapidly throughout sheets of cardiac muscle and cause coordinated contractions. Some cardiac muscle cells are pacemaker cells that generate and conduct electrical signals.
- **Smooth muscle** provides contractile force for internal organs. Smooth muscle cells respond to stretch and to neurotransmitters from the autonomic nervous system. **Review Figure 48.8, ANIMATED TUTORIAL 48.2**
- In skeletal muscle, a single action potential causes a minimum unit of contraction called a **twitch**. Twitches occurring in rapid succession can be summed, thus increasing the strength of contraction. Maximum sustained tension is known as **tetanus**. **Review Figure 48.10**

48.2 What Determines Muscle Performance?

- **Slow-twitch fibers** facilitate extended, aerobic work; **fast-twitch fibers** generate maximum forces for short periods of time. The ratio of slow-twitch to fast-twitch fibers in the muscles of an individual is largely genetically determined. **Review Figure 48.11**
- The force that a muscle fiber can produce depends on its initial state of extension or contraction. **Review Figure 48.12**
- Anaerobic exercise stimulates the enlargement of muscle fibers through production of new microfilaments. Aerobic exercise stimulates greater oxidative capacity of muscle fibers.
- Muscle performance depends on a supply of ATP. Available ATP and creatine phosphate can fuel maximum tension instantaneously but are exhausted within seconds. Glycolysis can regenerate ATP rapidly, but this process is inhibited by accumulation of lactic acid. Oxidative metabolism delivers ATP more slowly but can continue to do so for a long time. **Review Figure 48.13**

48.3 How Do Skeletal Systems and Muscles Work Together?

- **Skeletal systems** provide supports against which muscles can pull.
- **Hydrostatic skeletons** are fluid-filled body cavities that can be squeezed by muscles. **Review Figure 48.14**
- Exoskeletons are hardened outer surfaces to which internal muscles are attached.
- **Endoskeletons** are internal systems of rigid rodlike, platelike, and tubelike supports, consisting of **bone** and **cartilage** to which muscles are attached. **Review Figure 48.15**
- Bone is continually remodeled by **osteoblasts**, which lay down new bone, and **osteoclasts**, which erode bone. **Review Figure 48.16**
- Bones develop from connective tissue membranes (**membranous bone**) or from cartilage (**cartilage bone**) through ossification. Cartilage bone can grow until centers of ossification meet. **Review Figure 48.17**
- Bone can be **compact** (solid and hard), or **cancellous** (containing numerous internal spaces). Most of the compact bone of mammals is composed of **Haversian systems**. **Review Figure 48.18**
- **Joints** enable muscles to power movements in different directions. Muscles and bones work together around joints as systems of levers. **Review Figures 48.19, 48.21, WEB ACTIVITY 48.3**
- **Tendons** connect muscles to bones; **ligaments** connect bones to one another. **Review Figure 48.20**

SELF-QUIZ

- Smooth muscle differs from both cardiac and skeletal muscle in that
 - it can act as a pacemaker for rhythmic contractions.
 - contractions of smooth muscle are not due to interactions between neighboring microfilaments.
 - neighboring cells are electrically connected by gap junctions.
 - neighboring cells are tightly coupled by intercalated discs.
 - the membranes of smooth muscle cells are depolarized by stretching.
- Fast-twitch fibers differ from slow-twitch fibers in that
 - they are more common in the leg muscles of champion sprinters than marathon runners.
 - they have more mitochondria.
 - they fatigue less rapidly.
 - their abundance is more a product of training than of genetics.
 - they are more common in postural muscles than in finger muscles.

3. The role of Ca^{2+} in the control of muscle contraction is to
 - a. cause depolarization of the T tubule system.
 - b. change the conformation of troponin, thus exposing myosin-binding sites.
 - c. change the conformation of myosin heads, thus causing microfilaments to slide past each other.
 - d. bind to tropomyosin and break actin–myosin cross-bridges.
 - e. block the ATP-binding site on myosin heads, enabling muscles to relax.
4. Fifteen minutes into a 10-k run, what is the major energy source of the leg muscles?
 - a. Preformed ATP
 - b. Glycolysis
 - c. Oxidative metabolism
 - d. Pyruvate and lactate
 - e. High-protein drink consumed right before the race
5. Which statement about skeletal muscle contraction is *not* true?
 - a. A single action potential at the neuromuscular junction is sufficient to cause a muscle to twitch.
 - b. Once maximum muscle tension is achieved, no ATP is required to maintain that level of tension.
 - c. An action potential in the muscle cell activates contraction by releasing Ca^{2+} into the sarcoplasm.
 - d. Summation of twitches leads to a graded increase in the tension that can be generated by a single muscle fiber.
 - e. The tension generated by a muscle can be varied by controlling how many of its motor units are active.
6. Which statement about the structure of skeletal muscle is *true*?
 - a. The light bands of the sarcomere are the regions where actin and myosin filaments overlap.
 - b. When a muscle contracts, the A bands of the sarcomere lengthen.
 - c. The myosin filaments are anchored in the Z lines.
 - d. When a muscle contracts, the H zone of the sarcomere shortens.
 - e. The sarcoplasm of the muscle cell is contained within the sarcoplasmic reticulum.
7. Insects can beat their wings at exceptionally high frequencies because
 - a. their wing muscles have mostly fast-twitch fibers.
 - b. their motor neurons can fire action potentials at a very high frequency.
 - c. their wings have exoskeletal supports.
 - d. their wing muscles have extensive sarcoplasmic reticulum that cycles Ca^{2+} very fast.
 - e. their wing muscles can generate a rapid oscillation of contraction asynchronous with motor neuron firing.
8. The long bones of our arms and legs are strong and can resist both compressional and bending forces because
 - a. they are solid rods of compact bone.
 - b. their extracellular matrix contains crystals of calcium carbonate.
 - c. their extracellular matrix consists mostly of collagen and polysaccharides.
 - d. they have a high density of osteoclasts.
 - e. they consist of lightweight cancellous bone with an internal meshwork of supporting elements.
9. If we compare the jaw and knee joints as lever systems,
 - a. the jaw joint can apply greater compressional forces.
 - b. their ratios of power arm to load arm are about the same.
 - c. the knee joint has greater rotational abilities.
 - d. the knee joint has a greater ratio of power arm to load arm.
 - e. only the jaw is a hinged joint.
10. Which statement about skeletons is *true*?
 - a. They can consist of mostly cartilage.
 - b. Hydrostatic skeletons cannot be used for locomotion.
 - c. An advantage of exoskeletons is that they can continue to grow throughout the life of the animal.
 - d. External skeletons must remain flexible, so they never include calcium carbonate crystals, as bones do.
 - e. Internal skeletons consist of four different types of bone: compact, cancellous, membranous, and Haversian.

FOR DISCUSSION

1. You can see from the structure of a sarcomere that it can shorten only by a certain percentage of its resting length. Yet muscles can cause a wide variety of ranges of movement—compare the range of movement of a toe and a leg. What are two adaptive design features of muscles and skeletons that can maximize a muscle's ability to cause a greater range of movement of an appendage?
2. If athletes train up until a day before competition and then take a day of rest, performance in which types of events will be most affected by what they eat during the rest day?
3. Wombats are powerful digging animals, and kangaroos are powerful jumping animals. How do you think their leg structures compare in terms of their designs as lever systems?
4. Why are ducks better long-distance fliers than chickens?
5. If an adolescent breaks a leg bone close to the ankle joint, after the break heals, that leg may not grow as long as the other one. Why?

ADDITIONAL INVESTIGATION

For aerobic exercise endurance, the most important limiting factor is muscle glycogen reserve, but the muscles also use glucose from the blood. How would you design an experiment to test

whether or not carbohydrate intake during exercise improves endurance, and if it does, what its effect on the sparing of muscle glycogen is?

Why do elephants have long noses?

Elephants use their trunks in a variety of ways. They pluck leaves from trees and pull up plants from the ground; they pick up objects ranging in size from trees to seeds; they suck in water and squirt it into their mouths; they spray water and dust over their bodies; they smell the air around them; they communicate by touch; and mothers can wallop their calves when they misbehave.

Of course, elephants also use their trunks to breathe. This function takes on special interest when elephants go into deep water—for example, to cross rivers. Elephants can swim or walk on the bottom. In either case, they use their trunks as snorkels. As long as the tip of the trunk is above water, an elephant can breathe.

You may be familiar with diving using a snorkel about a foot long. When you want to dive deeper, you hold your breath. Water is heavy, and as you swim deeper, water

pressure increases and presses on your body. The air in your lungs is compressible, but the tissues of your body are not. So as you swim deeper, the volume of your lungs decreases.

Think what would happen if you tried to breathe through a long snorkel in deep water. Because the snorkel would be open to the air above, the pressure in your lungs would be at water surface level pressure, but the surrounding water would be pressing on your body. To expand your lungs, you would have to exert enough force to push against the surrounding water. Not so easy! Unlike elephants, we solve this problem with scuba equipment; by breathing air from a pressurized tank with a regulator valve, we keep the air in our lungs at the same pressure as the surrounding water.

The chest of a snorkeling elephant can be 3 meters below the surface—and for every 3 meters, the water pressure increases by 0.3 atmospheres. Even if an elephant's respiratory muscles were strong enough to work against this pressure, there would be a serious problem for the blood vessels lining the cavity in which the lungs are suspended. The pressure difference across the walls of those blood vessels is the difference between the pressure in the vessels (blood pressure plus water pressure) and the air pressure at the surface (where the trunk opens to the air). If the blood vessels couldn't withstand that pressure difference, they would rupture and fill the chest cavity with blood.

Proboscis as Snorkel Elephants can cross deep bodies of water either swimming or by walking on the bottom—whichever will allow it to keep its trunk above water.

Breathing Under Water Adapted to the aquatic life, fishes such as this whitetip shark have gills that extract respiratory gases from the water. The human cannot “breathe” water, so to enter this environment, he must carry a supply of respiratory gases in a scuba tank.

How does a snorkeling elephant avoid such damage? In all mammals except elephants, the surfaces of the lungs and the chest cavity move easily against each other. As the lungs inflate and deflate, their surface slips and slides against that of the chest cavity. In elephants, however, dense connective tissue attaches the surface of the lungs to the surface of the chest cavity. This connective tissue acts as reinforcement for the fragile blood vessels on the surface of the chest cavity and prevents them from rupturing and filling the cavity with blood, which would destroy the function of the lungs—exchange of oxygen and carbon dioxide.

IN THIS CHAPTER we will explore adaptations of the respiratory systems of both water and air breathers for exchanging oxygen and carbon dioxide with the environment. We will first discuss the physical factors that limit these gas exchange systems and identify those factors that natural selection has optimized. We will then examine the gas exchange systems of insects, fishes, birds, and humans and describe the adaptations of the blood for transporting respiratory gases. Finally, we will see how respiratory gas exchange systems are controlled and regulated.

CHAPTER OUTLINE

- 49.1** What Physical Factors Govern Respiratory Gas Exchange?
- 49.2** What Adaptations Maximize Respiratory Gas Exchange?
- 49.3** How Do Human Lungs Work?
- 49.4** How Does Blood Transport Respiratory Gases?
- 49.5** How is Breathing Regulated?

49.1 What Physical Factors Govern Respiratory Gas Exchange?

Gas exchange systems are made up of gas exchange surfaces and the mechanisms that *ventilate* and *perfuse* those surfaces. The **respiratory gases** that organisms must exchange are oxygen (O_2) and carbon dioxide (CO_2). Cells need to obtain O_2 from the environment to produce an adequate supply of ATP by cellular respiration (see Chapter 9). CO_2 is an end product of cellular respiration, and it must be removed from the body to prevent toxic effects.

Diffusion is the only means by which respiratory gases are exchanged between an animal’s internal body fluids and the outside medium (air or water). There are no active transport mechanisms to move respiratory gases across biological membranes. Because diffusion is a physical process, knowing what physical factors influence rates of diffusion helps us understand the diverse adaptations of gas exchange systems. (You should review the discussion about the physical nature of diffusion in Section 6.3.)

Diffusion is driven by concentration differences

Diffusion results from the random motion of molecules, and the net movement of a molecule is down its concentration gradient. Concentrations in solutions are easy to think about because they are simply the amount of solute per volume of solution. Concentrations of gases are more complicated because the total number of gas molecules in a specified volume depends on pressure; there are twice as many gas molecules in a liter of gas under 2 atmospheres of pressure as there are in a liter under 1 atmosphere of pressure. Biologists express the concentrations of different gases in a mixture by the *partial pressures* of those gases.

First we have to know what the total pressure is, and we measure that with an instrument called a barometer. There are many types of barometers, but the classical one is a glass tube closed at one end and filled with mercury. This is inverted over a pool of mercury with the open end of the tube under the surface of the mercury. At sea level, the pressure exerted by the atmosphere supports, and therefore equals, a column of mercury in the tube that is about 760 mm high (depending on the weather). Therefore, **barometric pressure** (atmospheric pressure) at sea level is 760 mm of mercury (mm Hg). Because dry air is 20.9 percent O_2 , the **partial pressure of oxygen** (P_{O_2}) at sea level is 20.9 percent of 760 mm Hg, or about 159 mm Hg. If two gas mixtures are separated by a membrane permeable to O_2 , O_2 will diffuse from the mixture where its partial pressure is higher to the mixture where its partial pressure is lower.

Describing the concentration of respiratory gases in a liquid such as water is more complicated because another factor is involved—the solubility of the gas in the liquid. Thus, the actual amount of a gas in a liquid depends on the partial pressure of that gas in the gas phase in contact with the liquid as well as on the solubility of that gas in that liquid. However, the diffusion of the gas between the gaseous phase and the liquid still depends on the partial pressures of the gas in the two phases. Whether in air or water, the diffusion rate of a substance depends on its concentration gradient and on other factors that are expressed in *Fick's law of diffusion*.

Fick's law applies to all systems of gas exchange

Diffusion is a physical phenomenon that can be described quantitatively with a simple equation called **Fick's law of diffusion**. All environmental variables that limit respiratory gas exchange and all adaptations that maximize respiratory gas exchange are reflected in one or more components of this equation. Fick's law is written as

$$Q = DA \frac{P_1 - P_2}{L}$$

where

- Q is the rate at which a gas such as O_2 diffuses between two locations.
- D is the *diffusion coefficient*, which is a characteristic of the diffusing substance, the medium, and the temperature. For

example, perfume has a higher D than motor oil vapor, and all substances diffuse faster at higher temperatures and faster in air than in water. Temperature is not expressed explicitly in Fick's law because the diffusion coefficient is usually determined at room temperature (about 20°C).

- A is the cross-sectional area through which the gas is diffusing.
- P_1 and P_2 are the partial pressures of the gas at the two locations.
- L is the path length, or distance, between the two locations.

Therefore, $(P_1 - P_2)/L$ is a *partial pressure gradient*.

Animals can maximize D for respiratory gases by using air rather than water as their gas exchange medium whenever possible. All other adaptations for maximizing respiratory gas exchange must influence the surface area (A) for gas exchange or the partial pressure gradient across that surface area.

Air is a better respiratory medium than water

The slow diffusion of O_2 molecules in water affects both air- and water-breathing animals. Eukaryotic cells carry out cellular respiration in their mitochondria, which are located in the cytoplasm—an aqueous medium. Cells are bathed in extracellular fluid—also an aqueous medium. In addition, all respiratory surfaces must be protected from drying out by a thin film of fluid through which O_2 must diffuse. Even in air-breathing animals, the slow rate of O_2 diffusion in water limits the efficiency of O_2 distribution from gas exchange surfaces to the sites of cellular respiration.

Diffusion of O_2 in water is so slow that even animal cells with low rates of metabolism can be no more than a few millimeters away from a good source of environmental O_2 . Therefore, there are severe size and shape limits on the many species of invertebrates that lack internal systems for distributing O_2 . Most of these species are very small, but some have grown larger by evolving a flat, thin body with a large external surface area (**Figure 49.1A**). Others have a very thin body built around a central cavity through which water can circulate (**Figure 49.1B**). A critical factor enabling larger, more complex animal bodies has been the evolution of specialized respiratory systems with large surface areas for enhancing gas exchange (**Figure 49.1C**).

O_2 can be obtained more easily from air than from water for several reasons:

- The O_2 content of air is much higher than the O_2 content of an equal volume of water. The maximum O_2 content of a bubbling stream in equilibrium with air is less than 10 ml of O_2 per liter of water. The O_2 content of the air over the stream is about 200 ml of O_2 per liter of air.

(A) *Pseudobiceros* sp.

Central cavity Channels

(B) *Callyspongia plicifera*

(C) *Ambystoma mexicanum*

49.1 Keeping in Touch with the Medium (A) No cell in the leaflike body of this marine flatworm is more than a millimeter away from seawater. (B) Sponges have body walls perforated by many channels, which allow water to flow between the outside world and a central cavity. No cell in the sponge is more than a millimeter away from seawater. (C) A feathery fringe of gills on this aquatic larval salamander provides a large surface area for gas exchange. Blood circulating through the gills comes into close contact with the respiratory medium.

- O_2 diffuses about 8,000 times more rapidly in air than in water. That is why the O_2 content of a stagnant pond can be zero only a few millimeters below the surface.
- An animal has to do work to move water or air over its gas exchange surfaces. More energy is required to move water than air because water is 800 times denser than air and about 50 times more viscous. You can appreciate how important these facts were for the movement of life to the terrestrial environment—there were fewer constraints on the evolution of higher metabolic rates.

High temperatures create respiratory problems for aquatic animals

Animals that use water for their respiratory exchange medium are in a double bind when environmental temperatures rise. Most water-breathing animals are *ectotherms*—their body temperatures are closely tied to the temperature of the water around them. As the water temperature rises, an ectotherm's body temperature and metabolic rate rise (see Figure 40.8). Thus, water breathers need more O_2 as the water gets warmer. But warm water holds less dissolved gas than cold water does (think of the gases that escape when you open a warm bottle of soda). In addition, if an animal performs work to move water across its gas exchange surfaces (as fishes do), it must expend more energy to breathe as water temperature rises. Therefore, as water temperature goes up, a water-breathing animal must extract more and more O_2 from an environment that is increasingly O_2 deficient, and a lower percentage of that O_2 is available to support activities other than breathing (Figure 49.2).

O_2 availability decreases with altitude

Just as a rise in water temperature reduces the supply of O_2 available to water-breathing animals, an increase in altitude reduces the O_2 supply for air breathers. At all altitudes, O_2 makes up 20.9 percent of the dry air; however, as you go up in altitude, the total amount of gas per unit volume decreases, as reflected in the barometric pressure. For example, at 5,800 m, barometric pressure is only half what it is at sea level, so the P_{O_2} at that altitude is only about 80 mm Hg. At the summit of Mount Everest (8,850 m), P_{O_2} is only about 50 mm Hg—roughly one-third what it is at sea level.

Because the movement of O_2 across respiratory gas exchange surfaces and into the body depends on diffusion, its rate of movement depends on the P_{O_2} difference between the air and the body fluids. Therefore, the drastically reduced P_{O_2} in the air at high altitudes constrains O_2 uptake. Because of this, mountain climbers attempting the highest peaks usually breathe O_2 from pressurized bottles.

CO_2 is lost by diffusion

Respiratory gas exchange is a two-way process: CO_2 diffuses out of the body as O_2 diffuses in. The direction and rate of diffusion of the respiratory gases across the exchange surfaces depend on the partial pressure gradients of the gases. The partial

49.2 The Double Bind of Water Breathers Fishes need more O_2 when the water is warmer, but warm water carries less O_2 than cold water.

pressure gradients of O_2 and CO_2 across these exchange surfaces are quite different. The amount of CO_2 in the atmosphere is extremely low (0.03%), so for air-breathing animals there is always a large concentration gradient for diffusion of CO_2 from the body to the environment. Whereas the partial pressure gradient for O_2 decreases with increasing altitude, the gradient driving CO_2 out of the body hardly changes. The partial pressure of CO_2 in the atmosphere is close to zero both at sea level and atop Mount Everest.

In general, getting rid of CO_2 is not a problem for water-breathing animals because CO_2 is much more soluble in water than is O_2 . Even in stagnant water, where the P_{CO_2} is higher than in moving water, the lack of O_2 becomes a problem for an animal long before CO_2 exchange difficulties arise.

49.1 RECAP

Respiratory gases are exchanged only by diffusion. Air is a better respiratory medium than water because a given volume of air has more O_2 than the same volume of water. O_2 diffuses faster in air than in water, and less work is required to move air over respiratory exchange surfaces.

- Describe how the variables in Fick's law of diffusion relate to respiratory systems. **See p. 1027**
- Why does a rise in water temperature create a double-bind situation for water-breathing animals? **See p. 1028 and Figure 49.2**
- Explain the concept of partial pressures of gases and how they relate to diffusion rates of O_2 and CO_2 at different altitudes. **See p. 1028**

Now that we have discussed the physical factors that influence diffusion rates of respiratory gases between animals and their environments, let's look at some of the adaptations that have evolved for maximizing respiratory gas exchange.

49.2 What Adaptations Maximize Respiratory Gas Exchange?

As you might expect from the components of Fick's law of diffusion, adaptations to maximize respiratory gas exchange can be categorized as those that:

- Increase the surface area for gas exchange
- Maximize the partial pressure difference driving diffusion
- Minimize the diffusion path length
- Minimize the diffusion that takes place in an aqueous medium

Respiratory organs have large surface areas

A variety of anatomical adaptations maximize the specialized body surface area (A) over which respiratory gases can diffuse. Water-breathing animals generally have *gills*, and air-breathing animals have *tracheae* or *lungs*. **External gills** are highly branched and folded extensions of the body surface that provide a large surface area for gas exchange with water (**Figure 49.3A**; see also Figure 49.1C). External gills are found in larval amphibians and in the larvae of many insects. Because they consist of thin, delicate tissues, external gills minimize the path length (L) traversed by diffusing molecules of O_2 and CO_2 . External gills are vulnerable to damage, however, and are tempting morsels for predators, so in many animals protective body cavities for gills have evolved. Such **internal gills** are found in most mollusks and arthropods and in all fishes (**Figure 49.3B**).

Lungs are internal cavities for respiratory gas exchange with air (**Figure 49.3C**). Their structure is quite different from that of gills. Lungs have a large surface area because they are highly divided; and because they are elastic, they can be inflated with air and deflated.

Insects have a respiratory gas exchange system consisting of a network of air-filled tubes called **tracheae** that branch through all tissues of the insect's body (**Figure 49.3D**). The terminal branches of these tubes are so numerous that they have an enormous surface area compared with the external surface area of the insect's body.

Transporting gases to and from exchange surfaces optimizes partial pressure gradients

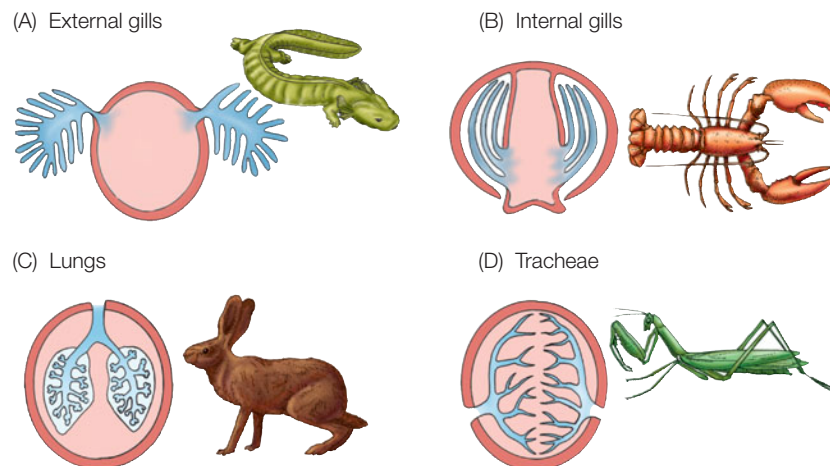

Partial pressure gradients $[(P_1 - P_2)/L]$ drive diffusion across gas exchange surfaces; the larger the gradient, the greater the rate of gas exchange. These gradients can be maximized in several ways:

- *Minimization of path length*: Very thin tissues in gills and lungs reduce the diffusion path length (L).
- *Ventilation*: Actively moving the external medium over the gas exchange surfaces (i.e., breathing) regularly exposes those surfaces to fresh respiratory medium containing maximum O_2 and minimum CO_2 concentrations. This maximizes the concentration gradient.
- *Perfusion*: Actively moving the internal medium (e.g., blood) over the internal side of the exchange surfaces transports CO_2 to those surfaces and O_2 away from them, thus maximizing the concentration gradients driving diffusion.

This chapter describes four gas exchange systems. First we will look at the unique gas exchange system of insects. Then we will describe two highly efficient gas exchange systems, fish gills and bird lungs. Lastly we examine the structure and function of human lungs.

Insects have airways throughout their bodies

The tracheal system that enables insects to exchange respiratory gases extends to all tissues in the insect body. Thus, respiratory gases diffuse through air most of the way to and from every cell. The insect respiratory system communicates with the outside environment through gated openings called *spiracles* in the sides of the abdomen (**Figure 49.4A,B**). The spiracles open to allow gas exchange and then close to decrease water loss. They open into tubes called *tracheae* that branch into even finer tubes,

49.3 Gas Exchange Systems Large surface areas (blue in these diagrams) for the diffusion of respiratory gases are common features of animals. External (A) and internal (B) gills are adaptations for gas exchange with water. Lungs (C) and tracheae (D) are organs for gas exchange with air.

49.4 The Tracheal Gas Exchange System of Insects (A) In insects, respiratory gases diffuse through a system of air tubes (tracheae) that open to the external environment through holes called spiracles. (B) The spiracles of a hawk-moth larva run down its sides. (C) A scanning electron micrograph shows an insect trachea dividing into smaller tracheoles and still finer air capillaries.

Acherontia atropos

or *tracheoles*, which end in tiny *air capillaries* that are the actual gas exchange surfaces (**Figure 49.4C**). In the insect's flight muscles and other highly active tissues, every mitochondrion is close to an air capillary.

Fish gills use countercurrent flow to maximize gas exchange

The internal gills of fishes are supported by *gill arches* that lie between the mouth cavity and the protective *opercular flaps* on the sides of the fish just behind the eyes (**Figure 49.5A**). Water flows *unidirectionally* into the fish's mouth, over the gills, and out from under the opercular flaps. Thus, the gills are continuously bathed with fresh water. This constant, one-way flow

49.5 Fish Gills (A) Water flows unidirectionally over the gills of a fish. (B) Gill filaments have a large surface area and thin tissues. (C) Blood flows through the lamellae in the direction opposite (left to right, in this depiction; small blue and red arrows) to the flow of water (right to left; large blue arrows) over the lamellae.

of water over the gills maximizes the P_{O_2} on the external gill surfaces. On the internal side of the gill membranes, the circulation of blood minimizes the P_{O_2} by sweeping O_2 away as rapidly as it diffuses across.

Gills have an enormous surface area for gas exchange because they are so highly divided. Each gill consists of hundreds of ribbonlike *gill filaments* (Figure 49.5B). The upper and lower flat surfaces of each gill filament are covered with rows of evenly spaced folds, or *lamellae*. The lamellae are the actual gas exchange surfaces. Because they are exceedingly thin, the path length (L) for diffusion of gases between blood and water is minimized. The surfaces of the lamellae consist of highly flattened epithelial cells, so the water and the fish's red blood cells are separated by little more than 1 or 2 micrometers.

The flow of blood perfusing the inner surfaces of the lamellae, like the flow of water over the gills, is unidirectional. *Afferent* blood vessels bring deoxygenated blood to the gills, while *efferent* blood vessels take oxygenated blood away from the gills (Figure 49.5C). Blood flows through the lamellae in the direction opposite to the flow of water over the lamellae. This **countercurrent flow** optimizes the P_{O_2} gradient between water and blood, making gas exchange more efficient than it would be in a system using concurrent (parallel) flow (Figure 49.6).

Some fishes, including anchovies, tuna, and certain sharks, ventilate their gills by swimming almost constantly with their mouths open. Most fishes, however, ventilate their gills by means of a two-pump mechanism. The closing and contracting of the mouth cavity pushes water over the gills, and the expansion of the opercular cavity prior to opening of the opercular flaps pulls water over the gills.

These adaptations for maximizing the surface area (A) for diffusion, minimizing the path length (L) for diffusion, and maximizing the P_{O_2} gradient allow fishes to extract an adequate supply of O_2 from meager environmental sources.

Birds use unidirectional ventilation to maximize gas exchange

Birds are remarkable for their ability to sustain high levels of activity for a long time—for example, on long-distance flights—even at high altitudes where mammals cannot even survive. The first team to climb Mount Everest was sur-

prised to see birds flying over the mountain when they themselves could barely move without supplemental O_2 . The highest recorded flight of a bird is from a vulture that collided with an airliner at 11,278 meters; a human could not exist at that altitude without supplemental O_2 . Yet the lungs of a bird are smaller than the lungs of a similar-sized mammal, and bird lungs expand and contract less during a breathing cycle than do mammalian lungs. Furthermore, bird lungs *are compressed* during inhalation and *expand* during exhalation.

The structure of bird lungs allows air to flow unidirectionally through the lungs, rather than bidirectionally through all the same airways, as it does in mammals. Because mammalian lungs are never completely emptied of air during exhalation, there is always some lung volume that is not ventilated with fresh air. The air remaining in lungs and airways after exhalation is called **dead space**. Bird lungs, by contrast, have very little dead space, and the fresh incoming air is not mixed with stale air. In this way, a high P_{O_2} gradient is maintained.

In addition to lungs, birds have **air sacs** at several locations in their bodies (Figure 49.7A). The air sacs are interconnected with each other, with the lungs, and with air spaces in some of the bones. The air sacs receive inhaled air, but they are not gas exchange surfaces. As in other air-breathing vertebrates, air enters and leaves a bird's gas exchange system through the **trachea** (commonly known as the *windpipe*, and not to be confused with the air-conducting tracheae of insects), which divides into smaller airways called **bronchi** (singular *bronchus*).

The bronchi divide into tubelike **parabronchi** that run parallel to one another through the lungs (Figure 49.7B). Branching off the parabronchi are numerous tiny *air capillaries*. Air flows through the parabronchi and diffuses into the air capillaries, which are the gas exchange surfaces. They are so numerous that they provide an enormous surface area for gas exchange. The parabronchi coalesce into larger bronchi that take the air out of the lungs and back to the trachea. Thus the anatomy of a bird's airways allows air to flow unidirectionally and continuously through the lungs.

49.6 Countercurrent Exchange Is More Efficient

In these models of concurrent and countercurrent gas exchange, the numbers represent the O_2 saturation percentages of blood and water. (A) In a concurrent exchanger, the saturation percentages of blood and water reach equilibrium halfway across the exchange surface. (B) A countercurrent exchanger allows more complete gas exchange because the water is always more O_2 -saturated than the blood; thus a gradient of O_2 saturation is maintained.

(A) Concurrent flow

(B) Countercurrent flow

Exchange is more complete with countercurrent flow.

In the countercurrent exchanger, a gradient of O_2 saturation exists over the full length of exchange surfaces.

(A) Avian air sacs and lungs

(B) Microscopic view of avian lung tissue

49.7 The Respiratory System of a Bird (A) Air sacs and air spaces in the bones are unique to birds. (B) Air flows through bird lungs unidirectionally in parabronchi. Air capillaries, the site of gas exchange, branch off the parabronchi.

The puzzle of how birds breathe was solved by placing small O_2 electronic sensors at different locations in birds' air sacs and airways. The birds were then exposed to pure O_2 for just a single breath, which made it possible to track that particular inhalation. The experiment demonstrated that a single breath remains in a bird's gas exchange system for two cycles of inhalation and exhalation, and that the air sacs work like bellows; inhalation expands the sacs, and exhalation compresses them to maintain a continuous and unidirectional flow of fresh air through the lungs (**Figure 49.8**).

The advantages of the bird gas exchange system are similar to those of fish gills. The air sacs keep fresh air flowing unidirectionally over the gas exchange surfaces. Thus, a bird can supply its gas exchange surfaces with a continuous flow of fresh air that has a P_{O_2} close to that of the ambient air. Even when the P_{O_2} of the ambient air is only slightly above that of the blood, O_2 can diffuse from air to blood.

Tidal ventilation produces dead space that limits gas exchange efficiency

Lungs evolved in the first "air-gulping" vertebrates as outpocketings of the digestive tract. Although their structure has evolved considerably, lungs remain dead-end sacs in all air-breathing vertebrates except birds. Because of this, ventilation cannot be constant and unidirectional but must be **tidal**: air flows in and exhaled gases flow out by the same route. Since the lungs and airways can never be completely emptied of air, they always contain dead space. We can easily measure the volumes of air exchanged during breathing, but we have to use an indirect method to measure the dead space contained in the lungs and airways.

49.8 The Path of Air Flow through Bird Lungs The air a bird takes in by breathing (blue) travels through the lungs in one direction, from the posterior to the anterior air sacs. Each breath of air remains in the system for two breathing cycles.

GO TO Animated Tutorial 49.1 • Airflow in Birds

A *spirometer* is a device that measures the volume of air breathed in and out (**Figure 49.9**). Using a human as an example, the amount of air that moves in and out per breath when at rest is called the **tidal volume (TV)** (about 500 ml for an average human adult). When we breathe in as much as possible, the additional volume is the **inspiratory reserve volume (IRV)**. Conversely, if we forcefully exhale as much air as possible, the additional amount of air expelled is the **expiratory reserve volume (ERV)**. The maximum capacity for air exchange in one breath, or the **vital capacity (VC)**, is the sum of TV + IRV + ERV. The vital capacity of an athlete is generally greater than that of a non-athlete, and vital capacity decreases with age because of stiffening of the lung tissue.

Vital capacity is not the entire lung capacity because, as mentioned above, there is dead space, also called the **residual volume (RV)**. We can't measure RV directly with the spirometer, but we can measure it indirectly using the *helium dilution method*. Briefly, a person breathes from a reservoir with a known volume of air containing a known amount of helium (He). The helium is not absorbed from the lungs, so it becomes evenly distributed between the lungs and the reservoir as the subject inhales and exhales. Because the fixed amount of He becomes dispersed in a larger volume of air, its concentration decreases. That decrease in He concentration enables us to calculate the subject's **functional residual volume (FRV)**, which is the ERV + RV. Since we *can* measure the ERV with the spirometer, we can subtract it and obtain the RV.

— yourBioPortal.com —

GO TO Working with Data • Calculating the Functional Residual Volume

Why is the RV important? Referring to Figure 49.9, you will see that for a normal person the ERV is about 1000 ml and the RV is 1000 ml. Thus the FRV is 2000 ml, but the tidal volume is only 500 ml. Thus, the air that reaches the alveoli with each breath consists of only 500 cc of fresh air diluted by 2000 cc of stale air. The maximum P_{O_2} in this mixed air is much below the P_{O_2} of the outside air, and because of the tidal ventilation pattern, the P_{O_2} in the alveoli is steadily dropping during the breathing cycle. The RV is important because it contributes to the FRC and to the dilution of the O_2 in the inhaled air. Any disease or condition that increases the RV (such as emphysema or pulmonary fibrosis) compromises a patient's respiratory ability. Similarly, considering the mixing of fresh air with the FRV, you can understand why reductions in tidal volume can be a prob-

lem—and therefore why patients recovering from surgery are encouraged to breathe deeply, even if it hurts.

Offsetting the inefficiencies of tidal breathing, mammalian lungs have some design features to maximize the rate of gas exchange: an enormous surface area and a very short path length for diffusion.

49.2 RECAP

The major adaptations that increase animals' efficiency of respiratory gas exchange are a large surface area for exchange and a maximized concentration gradient across that surface.

- Describe three different ways that the concentration gradient for gas exchange is maximized across fish gills. **See pp. 1030–1031 and Figures 49.5 and 49.6**
- What respiratory adaptations enable birds to fly at extremely high altitudes? **See pp. 1031–1032 and Figures 49.7 and 49.8**
- Explain why residual volume limits the efficiency of tidal breathing. **See pp. 1032–1033 and Figure 49.9**

Despite their limitations, mammalian lungs serve the respiratory needs of mammals well. Let's look at the human respiratory system as an example.

(A)

49.10 The Human Respiratory System

The diagrams trace the hierarchy of human respiratory structures, from the airways to the minuscule alveoli.

The bronchi are the major air passageways of the lungs. They lead to the bronchioles, which are finely branched, as are the blood vessels.

49.3 How Do Human Lungs Work?

In humans, air enters the lungs through the oral cavity or nasal passage, which join together in the *pharynx* (Figure 49.10A). Below the pharynx, the esophagus conducts food to the stomach, and the trachea leads to the lungs. At the beginning of this airway is the *larynx*, or voice box, which houses the vocal cords. The larynx is the “Adam’s apple” that you can see or feel on the front of your neck. The trachea is about 2 cm in diameter. Its thin walls are prevented from collapsing by C-shaped bands of cartilage as air pressure changes during the breathing cycle. If you run your fingers down the front of your neck just below your larynx, you can feel a few of these bands of cartilage.

The trachea branches into two bronchi, one leading to each lung. The bronchi branch repeatedly to generate a treelike structure of progressively smaller airways extending to all regions of the lungs. After four branchings, the cartilage supports disappear, marking the transition to **bronchioles**. After about 16 branchings, the bronchioles are less than a millimeter in diameter, and tiny, thin-walled air sacs called **alveoli** begin to appear. Alveoli are the sites of gas exchange. After alveoli begin to appear, about six more branchings of the airways occur that end in clusters of alveoli (Figure 49.10B). Because the airways conduct air only to and from the alveoli and do not themselves participate in gas exchange, their volume is dead space.

Human lungs have about 300 million alveoli. Although each alveolus is very small, their combined surface area for diffusion of respiratory gases is about 70 square meters—about one-fourth the size of a basketball court. Each alveolus is made of very thin cells. Between and surrounding the alveoli are networks of capillaries whose walls are also made up of exceedingly thin cells. Where capillary meets alveolus, very little tissue separates them (Figure 49.10C), so the length of the diffusion path between air and blood is less than 2 micrometers.

Emphysema, a condition in which inflammation damages and eventually destroys the walls of the alveoli, is the fourth leading cause of death in the United States. As a result of this disease the lungs have fewer but larger alveoli, the RV increases, and the lungs lose elasticity. Although genetic factors can contribute to emphysema, the principal cause of the disease is smoking.

Respiratory tract secretions aid ventilation

Mammalian lungs produce two secretions that do not directly influence their gas exchange but do affect the process of ventilation: mucus and surfactant.

Many cells lining the airways produce sticky mucus that captures bits of dirt and microorganisms that are inhaled. Other cells lining the airways have cilia whose beating continually sweeps the mucus, with its trapped debris, up toward the pharynx, where it can be swallowed or spit out. This phenomenon, called the *mucus escalator*, can be adversely affected by inhaled pollutants. Smoking one cigarette can immobilize the cilia of the airways for hours. A smoker’s cough results from the need to clear the obstructing mucus from the airways when the mucus escalator is out of order. The genetic disease *cystic fibrosis* causes

respiratory problems by affecting the respiratory mucus (see Figure 17.3B).

A **surfactant** is a substance that reduces the surface tension of a liquid. **Surface tension** gives the surface of a liquid such as water the properties of an elastic membrane, and it is why certain insects, such as water-striders, can walk on water. As discussed in Section 2.4, surface tension is the result of chemical forces of attraction between water molecules. The attractive forces working on the water molecules at the surface pull from below and from the sides but not from above. This imbalance of forces creates surface tension. The thin film of fluid covering the air-facing surfaces of the alveoli has surface tension that contributes to the lungs’ elasticity. To inflate the lungs, enough force has to be generated to overcome both the elasticity of the lung tissue and the surface tension in the alveoli.

Lung surfactant is a fatty, detergent-like substance that is critical for reducing the work necessary to inflate the lungs. Certain cells in the alveoli release surfactant molecules when they are stretched. If a baby is born more than a month prematurely, these cells may not have developed the ability to produce surfactant. A baby with this condition, known as *respiratory distress syndrome*, will have great difficulty breathing and may die from exhaustion and lack of O₂. Common treatments for premature babies have been to put them on respirators to assist their breathing and to give them hormones to speed lung development. A new approach is to apply surfactant to the lungs via an aerosol.

Lungs are ventilated by pressure changes in the thoracic cavity

Human lungs are suspended in the **thoracic cavity**, a closed compartment bounded on the bottom by a sheet of muscle called the **diaphragm** (see Figure 49.10A). Each lung is covered by a continuous sheet of tissue called the **pleural membrane** that also lines the thoracic cavity adjacent to that lung. There is no real space between the pleural membranes of the lung and the thoracic cavity, but there is a thin film of fluid. This fluid lubricates the inner surfaces of the pleural membranes so they can slip and slide against each other during breathing movements. Just as we mentioned above in the explanation of surface tension, there are forces of attraction between the molecules of fluid in the pleural membranes. As a result, it is difficult to pull the pleural membranes apart. Think of two wet panes of glass or two wet microscope slides; you can slide them past each other, but it is difficult to separate them. While the inner surfaces of the pleural membranes are “stuck” to each other by surface tension, the outer surfaces are attached to the wall of the thoracic cavity and to the surface of the lung.

Inhalation and exhalation involve changes in the volume of the thoracic cavity (Figure 49.11). Because the pleural membranes are attached to the walls of the thoracic cavity, and because the pleural membranes covering the cavity wall and the lung surface are stuck to each other by surface tension, any attempt to increase the volume of the thoracic cavity increases the tension between the pleural membranes. Even between breaths, there is tension between the pleural membranes because the rib cage is pulling outward and the elasticity of the

49.11 Into the Lungs and Out Again

(A) Inhalation is an active process spurred by contraction of the diaphragm. (B) Exhalation generally is a passive process as the diaphragm relaxes. (C) There is always negative pressure in the pleural cavity—the space between the pleural membranes. Variations in that negative pressure cause the lungs to inflate and deflate during the breathing cycle.

yourBioPortal.com

GO TO Animated Tutorial 49.2 • Airflow in Mammals

lung tissue is pulling inward. This slight negative pressure keeps the alveoli partly inflated even at the end of an exhalation. If the thoracic cavity is punctured—by a knife wound, for example—air can leak into the space between the pleural membranes and cause the lung to deflate. If the wound is not sealed, breathing movements pull air in between the pleural membranes rather than into the lung (a “sucking chest wound”), and there is no ventilation of the alveoli in that lung—a condition called “collapsed lung.”

At rest, inhalation is initiated by contraction of the muscular diaphragm (see Figure 49.11A). As the domed diaphragm contracts, it pulls down, expanding the thoracic cavity and pulling on the pleural membranes. Since the pleural membranes cannot separate because of the surface tension of the thin film of fluid between them, they pull on the lungs. The lungs are not a closed cavity; they have an airway to the atmosphere, and they can expand. When the diaphragm contracts, air rushes in through the trachea from the outside and the lungs expand. Exhalation begins when contraction of the diaphragm ceases. As the diaphragm relaxes, the elastic recoil of the lung tissues pulls the diaphragm up and pushes air out through the airways (see Figure 49.11B). When a person is at rest, inhalation is an active process and exhalation is a passive process.

The diaphragm is not the only muscle that can change the volume of the thoracic cavity. Between the ribs are two sets of **intercostal muscles**. The *external intercostal muscles* expand the thoracic cavity by lifting the ribs up and outward. The *internal intercostal muscles* decrease the volume of the thoracic cavity by pulling the ribs down and inward. During strenuous exercise, the external intercostal muscles increase the volume of air inhaled, making use of the inspiratory reserve volume, and the internal intercostal muscles increase the amount of air exhaled, making use of the expiratory reserve volume. The abdominal muscles can also aid in breathing. When they contract, they cause the abdominal contents to push up on the diaphragm and thereby contribute to the expiratory reserve volume.

Remember that ventilation and perfusion work together to maximize the partial pressure gradients across the gas exchange surface. Ventilation delivers O_2 to the environmental side of the exchange surface, where it diffuses across and is swept away by the perfusing blood, which carries it to the tissues that need it. The reverse is true for the exchange of CO_2 . Perfusion delivers CO_2 to the exchange surface, where it diffuses out and is swept away by ventilation.

49.3 RECAP

The mammalian respiratory system consists of a highly branching system of airways that lead to blind end sacs called alveoli which are the gas exchange surfaces. Respiratory muscles ventilate the alveoli by creating pressure differences between the lungs and the outside air. CO_2 and O_2 are exchanged across thin capillary and alveoli walls by diffusion.

- Describe the path that a breath of air takes from the nose to the gas exchange surfaces. **See p. 1035 and Figure 49.10**
- What roles do mucus and surfactant play in maintaining the function of the mammalian respiratory system? **See p. 1035**
- Explain the anatomical and functional relationships between the thoracic cavity, the pleural membranes, and the lungs. **See pp. 1035–1036 and Figure 49.11**

Now that we have discussed how respiratory gases get to and from the environmental side of the gas exchange membranes through ventilation, we can look at how these gases get to and from the internal side of the gas exchange membranes through perfusion.

49.4 How Does Blood Transport Respiratory Gases?

Perfusion of the lungs is one of the functions of the circulatory system. The circulatory system uses a pump (the heart) and a network of vessels to transport blood around the body. Circulatory systems are the subject of Chapter 50, so here we will discuss only one aspect of perfusion: how blood transports respiratory gases.

The liquid part of blood, the *blood plasma*, carries some O_2 in solution, but its ability to transport this non-polar molecule is limited. The blood plasma of a human can contain in solution only about 0.3 ml of O_2 per 100 ml of plasma, which is inadequate to support even basal metabolism. However, the blood of most animals, vertebrate and invertebrate, contains molecules that reversibly bind O_2 and thus augment its transport capacity. These molecules pick up O_2 where P_{O_2} is high and release it where P_{O_2} is lower. There are many O_2 transport molecules in the animal kingdom, but in vertebrates this role is played by the protein hemoglobin con-

tained in red blood cells. Hemoglobin increases the capacity of blood to transport O_2 by about 60-fold, making high levels of metabolism possible.

Hemoglobin combines reversibly with O_2

Red blood cells contain enormous numbers of hemoglobin molecules. **Hemoglobin** is a protein consisting of four polypeptide subunits (see Figure 3.9), each of which surrounds a *heme group*—an iron-containing ring structure that can reversibly bind a molecule of O_2 . Thus, each hemoglobin molecule can bind up to four O_2 molecules, enabling the blood to carry a large amount of O_2 to the body's tissues.

Hemoglobin's ability to pick up or release O_2 depends on the P_{O_2} in its environment. When the P_{O_2} of the blood plasma is high, as it usually is in the lung capillaries, each hemoglobin molecule can carry its maximum load of four O_2 molecules. As the blood circulates through the rest of the body, it releases some of the O_2 it is carrying when it encounters lower P_{O_2} values (**Figure 49.12**).

The relation between P_{O_2} and the amount of O_2 bound to hemoglobin is not linear but S-shaped (sigmoidal). The hemoglobin–oxygen binding curve in Figure 49.12 reflects interactions between the four subunits of the hemoglobin molecule. At low P_{O_2} values, only one subunit will bind an O_2 molecule. When it does so, the shape of that subunit changes, altering the quaternary structure of the whole hemoglobin molecule. That structural change makes it easier for the other subunits to bind an O_2 molecule; that is, their O_2 *affinity* is increased. Therefore, a smaller increase in P_{O_2} is necessary to get the hemoglobin molecules to bind a second O_2 molecule (that is, to become 50% saturated) than was necessary to get them to bind one O_2 molecule

49.12 Binding of O_2 to Hemoglobin Depends on P_{O_2} Hemoglobin in blood leaving the lungs is 100 percent saturated (four O_2 molecules are bound to each hemoglobin molecule). Most hemoglobin molecules drop only one of their four O_2 molecules as they circulate through the body and are still 75 percent saturated when the blood returns to the lungs. The steep portion of this O_2 -binding curve comes into play when tissue P_{O_2} falls below the normal 40 mm Hg, at which point hemoglobin “unloads” its O_2 reserves.

Lama glama

49.13 Oxygen-Binding

Adaptations Myoglobin and the different hemoglobins have different O_2 -binding properties adapted to different circumstances. The hemoglobin of South American camelids, for example, is adapted for binding O_2 at high altitudes, where P_{O_2} is low. Fetal hemoglobin has a higher affinity for O_2 than does maternal hemoglobin, facilitating O_2 transfer in the placenta. When high metabolism lowers the pH of the blood, hemoglobin releases more of its O_2 .

yourBioPortal.com

GO TO Web Activity 49.2 • Oxygen-Binding Curves

(to become 25% saturated). This influence of O_2 binding by one subunit on the O_2 affinity of the other subunits is called **positive cooperativity**.

Once the third O_2 molecule is bound, the relationship seems to change, as a larger increase in P_{O_2} is required for the hemoglobin to reach 100 percent saturation. This upper bend of the sigmoid curve is due to a probability phenomenon. The closer we get to having all subunits occupied, the less likely it is that any particular O_2 molecule will find a place to bind. Therefore, it takes a relatively greater P_{O_2} to achieve 100 percent saturation.

The O_2 -binding/dissociation properties of hemoglobin help get O_2 to the tissues that need it most. In the lungs, where the P_{O_2} is about 100 mm Hg, hemoglobin is 100 percent saturated. The P_{O_2} in blood returning to the heart from the body is usually about 40 mm Hg. You can see in Figure 49.12 that at this P_{O_2} , the hemoglobin is still about 75 percent saturated. This means that as the blood circulates around the body, it releases only about one in four of the O_2 molecules it carries. This system seems inefficient, but it is really quite adaptive, because the hemoglobin keeps 75 percent of its O_2 in reserve to meet peak demands of highly active tissues.

When a tissue becomes starved of O_2 and its local P_{O_2} falls below 40 mm Hg, the hemoglobin flowing through that tissue is on the steep portion of its binding/dissociation curve. That means relatively small decreases in P_{O_2} below 40 mm Hg will result in the release of lots of O_2 to the tissue. Thus hemoglobin is very effective in making O_2 available to tissues precisely when and where it is needed most.

The O_2 transport function of hemoglobin can rapidly and tragically be disrupted by a common by-product of incomplete combustion: carbon monoxide (CO). If CO from a faulty heating system, engine exhaust, or burning charcoal accumulates in a closed space, the results can be deadly. Because CO binds to hemoglobin with a 240-fold higher affinity than O_2 , it prevents hemoglobin from transporting O_2 . In the United States, more than 5,000 people die each year from CO poisoning.

Myoglobin holds an O_2 reserve

Muscle cells have their own O_2 -binding molecule, *myoglobin*. Myoglobin consists of just one polypeptide chain associated

with an iron-containing ring structure that can bind one O_2 molecule. Myoglobin has a higher affinity for O_2 than hemoglobin does, so it picks up and holds O_2 at P_{O_2} values at which hemoglobin is releasing its bound O_2 (Figure 49.13).

Myoglobin facilitates the diffusion of O_2 in muscle cells and provides an O_2 reserve for times when metabolic demands are high and blood flow is interrupted. Interruption of blood flow in muscles is common because contracting muscles squeeze blood vessels. When tissue P_{O_2} values are low and hemoglobin can no longer supply more O_2 , myoglobin releases its bound O_2 . Diving mammals such as seals have high concentrations of myoglobin in their muscles, which is one reason they can stay under water for so long. (We discuss more adaptations for diving in Chapter 50.) Even in nondiving animals, muscles called on for extended periods of work frequently have more myoglobin than muscles that are used for short, intermittent periods, as noted in Section 48.2.

Hemoglobin's affinity for O_2 is variable

Various factors influence the O_2 -binding/dissociation properties of hemoglobin, thereby influencing O_2 delivery to tissues. Three of those factors are the chemical composition of the hemoglobin, the blood pH, and the presence of 2,3-bisphosphoglyceric acid (BPG) in red blood cells.

HEMOGLOBIN COMPOSITION There is more than one type of hemoglobin, because the chemical composition of the polypeptide chains that form the hemoglobin molecule varies. The normal hemoglobin of adult humans has two each of two kinds of polypeptide chains—two α -globin chains and two β -globin chains—and the O_2 -binding characteristics shown in Figure 49.13.

Before birth, the human fetus has a different form of hemoglobin, consisting of two α -globin and two γ -globin chains. The functional difference between fetal and adult hemoglobin is that fetal hemoglobin has a higher affinity for O_2 . Therefore, the fetal hemoglobin–oxygen binding/dissociation curve is shifted to the left compared with that for adults (see Figure 49.13). You can see from these curves that if both types of hemoglobin

are at the same P_{O_2} (as they are in the placenta), fetal hemoglobin will pick up O_2 that the maternal hemoglobin releases. This difference in O_2 affinities enables the efficient transfer of O_2 from the mother's blood to the fetus's blood.

South American camelids—llamas, alpacas, guanacos, and vicuñas—are native to the Andes Mountains. In the natural habitat of these mammals, more than 5,000 m above sea level, the P_{O_2} is below 85 mm Hg, and the P_{O_2} in their lungs is about 50 mm Hg. To increase their chances of survival in their low O_2 environment, the hemoglobins of these camelids have O_2 -binding/dissociation curves to the left of those of most other mammals—in other words, their hemoglobin can become saturated with O_2 at lower P_{O_2} values than those of other mammals.

HEMOGLOBIN AND pH The O_2 -binding properties of hemoglobin are also influenced by physiological conditions. The influence of pH on the function of hemoglobin is known as the **Bohr effect**. As blood passes through metabolically active tissue such as exercising muscle, it picks up acidic metabolites such as lactic acid, fatty acids, and CO_2 . As a result, blood pH falls. The excess H^+ binds preferentially to deoxygenated hemoglobin and decreases its affinity for O_2 and the O_2 -binding/dissociation curve of hemoglobin shifts to the right (see Figure 49.13). This shift means the hemoglobin will release more O_2 in tissues where pH is low—another way that O_2 is supplied where and when it is most needed.

2,3-BISPHOSPHOGLYCERIC ACID BPG is a metabolite of glycolysis (see Figure 7.5). Mammalian red blood cells respond to low P_{O_2} by increasing their rate of glycolysis and thus producing more BPG, which is an important regulator of hemoglobin function. BPG, like excess H^+ , reversibly combines with deoxygenated hemoglobin and lowers its affinity for O_2 . The result is that at any P_{O_2} , hemoglobin releases more of its bound O_2 than it otherwise would. In other words, BPG shifts

the O_2 -binding/dissociation curve of mammalian hemoglobin to the right.

When humans go to high altitudes, or when they cease being sedentary and begin to exercise, their red blood cells are exposed to a lower P_{O_2} and their level of BPG goes up, making it easier for hemoglobin to deliver more O_2 to tissues. The reason fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve is that its γ -globin chains have a lower affinity for BPG than do the β -globin chains of adult hemoglobin.

CO_2 is transported as bicarbonate ions in the blood

Delivering O_2 to tissues is only half the respiratory function of blood. Blood also must take CO_2 , a metabolic waste product, away from tissues (Figure 49.14). CO_2 is highly soluble and readily diffuses through cell membranes, moving from its site of production in the tissues into the blood, where the partial pressure of CO_2 (P_{CO_2}) is lower. However, very little dissolved CO_2 is transported by the blood. Most CO_2 produced by the tissues is transported to the lungs in the form of **bicarbonate ions**, HCO_3^- . CO_2 is converted to HCO_3^- , transported to the lungs, and then converted back to CO_2 in several steps.

When CO_2 dissolves in water, some of it slowly reacts with the water molecules to form carbonic acid (H_2CO_3), some of which then dissociates into a proton (H^+) and a bicarbonate ion (HCO_3^-). This reversible reaction is expressed as follows:

In the extracellular fluid, the reaction between CO_2 and H_2O proceeds slowly. But it is a different story in the endothelial cells of the capillaries and in the red blood cells, where the enzyme *carbonic anhydrase* speeds up the conversion of CO_2 to H_2CO_3 .

49.14 Carbon Dioxide Is Transported as Bicarbonate Ions

Carbonic anhydrase in capillary endothelial cells and in red blood cells facilitates conversion of CO_2 produced by tissues into bicarbonate ions carried by the plasma. In the lungs, the process is reversed as CO_2 is exhaled.

The newly formed H_2CO_3 dissociates, and the resulting bicarbonate ions enter the plasma in exchange for Cl^- (see Figure 49.14). By converting CO_2 to H_2CO_3 , carbonic anhydrase reduces the P_{CO_2} in these cells and in the plasma, facilitating the diffusion of CO_2 from tissue cells to endothelial cells, plasma, and red blood cells. Some CO_2 is also carried in chemical combination with hemoglobin.

In the lungs, the reactions involving CO_2 and bicarbonate ions are reversed. Remember that an enzyme such as carbonic anhydrase only speeds up a reversible reaction; it does not determine its direction. The direction is determined by concentrations of reactants and products (see Section 6.1). Ventilation keeps the CO_2 concentration in the alveoli low, so CO_2 diffuses from the blood plasma into the alveoli, lowering the CO_2 concentration in the blood, which favors the conversion of HCO_3^- into CO_2 .

49.15 Breathing Is Controlled in the Brainstem Basic breathing rhythm is generated in the medulla and is modified by neurons in or above the pons.

49.4 RECAP

O_2 is transported from the lungs to the body's tissues in reversible combination with hemoglobin. Each hemoglobin molecule can reversibly combine with four O_2 molecules; the saturation of the binding sites is a function of the P_{O_2} in the hemoglobin's environment.

- Explain the advantage of having hemoglobin hold on to three O_2 molecules at the usual P_{O_2} of mixed venous blood. **See pp. 1037–1038 and Figure 49.12**
- How is the O_2 -binding/dissociation curve of hemoglobin influenced by pH? By BPG? By development from fetus to newborn infant? **See p. 1039 and Figure 49.13**
- How is CO_2 transported in the blood? **See pp. 1039–1040 and Figure 49.14**

We must breathe every minute of our lives, but we don't usually worry about it, or even think about it very often. In the next section we will examine how the regular breathing cycle is generated and controlled by the central nervous system.

49.5 How Is Breathing Regulated?

Breathing is an involuntary function of the central nervous system. The breathing pattern easily adjusts itself around other activities (such as speech and eating), and breathing rates change to match the metabolic demands of our bodies. How is this accomplished?

Breathing is controlled in the brainstem

The autonomic nervous system maintains breathing and modifies its depth and frequency to meet the body's demands for O_2 supply and CO_2 elimination. Breathing ceases if the spinal cord is severed in the neck region, showing that breathing is

generated in the brain. If the brainstem is cut just above the medulla (the segment of the brainstem just above the spinal cord), an irregular breathing pattern remains (Figure 49.15).

Groups of respiratory motor neurons in the medulla increase their firing rates just before an inhalation begins. As more and more of these neurons fire—and fire faster and faster—the diaphragm contracts. All of a sudden, the neurons stop firing, the

49.16 Carbon Dioxide Affects Breathing Rate The breathing mechanism, controlled by feedback to the medulla, is more sensitive to increased levels of CO_2 in arterial blood than to decreased amounts of O_2 . The intersection point occurs at normal (equilibrium) ventilation rate and blood gas levels.

diaphragm relaxes, and exhalation begins. Exhalation is usually a passive process that depends on the elastic recoil of the lung tissues. When breathing demand is high, however, as during strenuous exercise, motor neurons for the intercostal muscles are recruited to a greater extent than during tidal breathing, increasing both the inhalation and the exhalation volumes. Brain areas above the medulla modify breathing to accommodate speech, ingestion of food, coughing, and emotional states.

Regulating breathing requires feedback information

When breathing or metabolism changes, it alters the P_{O_2} and P_{CO_2} in the blood. We should therefore expect the blood levels of one or both of these gases to provide feedback information to the breathing rhythm generator in the medulla. Experiments in which subjects breathe air with different P_{O_2} and P_{CO_2} concentrations lead us to conclude that humans (and other mammals) are remarkably insensitive to falling levels of O_2 in arterial blood but are extremely sensitive to increases in CO_2 . That is, arterial P_{O_2} can deviate considerably from normal without causing much of an increase in ventilation rate, but even a small rise in arterial P_{CO_2} causes a large increase in ventilation (Figure 49.16). This relationship is reversed for water-breathing animals, in which O_2 is the primary feedback stimulus for gill ventilation.

We might ask whether it is an increase in the P_{CO_2} of the blood that stimulates increased breathing when we exercise. To answer this question, C. R. Bainton observed dogs running on treadmills at different speeds. As the speed of the treadmill increased, the dogs' respiratory gas exchange rate increased but their blood P_{CO_2} remained constant. Before concluding that blood P_{CO_2} does not control breathing rate, Bainton changed the experiment. Instead of increasing the speed of the treadmill, he gradually increased its slope so that the dogs were running at the same speed but were working harder because they were running uphill (Figure 49.17).

In this second experiment, the P_{CO_2} of the blood increased as the slope of the treadmill increased and as the respiratory gas exchange rate increased. Bainton concluded that the P_{CO_2} of the blood is the primary metabolic feedback information for breathing. However, when an animal starts to run or changes its running speed, additional feedback information from receptors in muscles and joints changes its sensitivity to CO_2 —an example

INVESTIGATING LIFE

49.17 Sensitivity of the Respiratory Control System Changes with Exercise

Experiments with dogs running on a treadmill show that sensitivity of the respiratory system to CO_2 changes when speed of running changes, but not when workload changes without a change in speed.

HYPOTHESIS Rising levels of blood CO_2 during exercise is the feedback signal that stimulates an increase in respiratory rate.

METHOD

1. Dogs are trained to run on a treadmill.
2. The trained dogs are equipped with instruments that measure their respiratory rate and with catheters that withdraw blood samples for measurement of CO_2 levels.
3. The dog runs with the treadmill set first at different speeds, and then with the slope of the treadmill elevated (which increases the workload).
4. Respiratory rate is plotted as a function of arterial CO_2 concentration.

RESULTS

CHANGES IN SPEED

Respiratory rate changes with running speed but CO_2 levels do not. The hypothesis is not supported.

CHANGES IN SLOPE

Respiratory rate and CO_2 levels both rise as workload increases. The hypothesis is supported.

CONCLUSION Arterial CO_2 level is the metabolic feedback signal that regulates respiration in response to workload.

FURTHER INVESTIGATION: Exposure to cold is another variable that increases respiration. How would you test whether cold-induced respiration is driven by elevated blood CO_2 levels?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

of feedforward information. As noted in Section 40.1, feedforward information can change the sensitivity or the set point of a regulatory system.

Where are partial pressures of gases in the blood sensed? The major site of P_{CO_2} sensitivity is an area on the ventral surface of the medulla, not far from the groups of neurons that generate the breathing rhythm. The primary sensitivity of these chemosensitive cells is not to CO_2 , however. Rather, they are stimulated by H^+ ions. The H^+ ion concentration, or pH, in the environment of these cells is a direct reflection of the P_{CO_2} of the

blood. When the P_{CO_2} of the blood is higher than that of the extracellular fluid in this area, CO_2 diffuses out of the blood. That CO_2 interacts with H_2O to form carbonic acid (H_2CO_3), which dissociates into H^+ ions and HCO_3^- ions as shown in Figure 49.14. The H^+ ions that are produced stimulate the chemosensitive cells that increase respiratory gas exchange.

49.18 Feedback Information Controls Breathing The body uses feedback information from chemosensors in the heart and brain to match breathing rate to metabolic demand.

Thus, even though we measure blood P_{CO_2} as the stimulus for breathing, the real stimulus is pH.

Sensitivity to blood P_{O_2} resides in nodes of neural tissue on the large blood vessels leaving the heart: the aorta and the carotid arteries (Figure 49.18). These **carotid** and **aortic bodies** are chemosensors. If the blood supply to these structures decreases, or if the blood P_{O_2} falls dramatically, the chemosensors are activated and send nerve impulses to the breathing control center. Although we are not very sensitive to changes in blood P_{O_2} , the carotid and aortic bodies can stimulate increases in breathing during exposure to very high altitudes or when blood volume or blood pressure is very low. Also, there is a synergism between CO_2 and O_2 sensing. When blood P_{CO_2} increases, there is an increased sensitivity to low O_2 and vice versa.

49.5 RECAP

The rhythmic contractions of the respiratory muscles that drive breathing are generated by neurons in the brainstem.

- What is the primary chemical stimulus for controlling the respiratory rate, and where is it sensed? **See p. 1040 and Figures 49.16 and 49.18**
- Explain what feedforward information is. Can you give an example of feedforward information in the respiratory control system? **See Figure 49.17**
- What are the functions of the carotid and aortic bodies? **See p. 1042 and Figure 49.18**

CHAPTER SUMMARY

49.1 What Physical Factors Govern Respiratory Gas Exchange?

- Most cells require a constant supply of O_2 and continuous removal of CO_2 . These **respiratory gases** are exchanged between an animal's body fluids and its environment by diffusion.
- **Fick's law of diffusion** shows how various physical factors influence the diffusion rate of gases. Adaptations to maximize respiratory gas exchange influence one or more variables of Fick's law.
- In water-breathing animals, gas exchange is limited by the low diffusion rate and low amount of O_2 in water. If water temperature rises, water-breathing animals face a double bind in that the amount of O_2 in water decreases, but their metabolism and the amount of work required to move water over the gas exchange surfaces increase. **Review Figure 49.2**

- In air, the **partial pressure of oxygen (P_{O_2})** decreases with altitude.

49.2 What Adaptations Maximize Respiratory Gas Exchange?

- Adaptations to maximize gas exchange include increasing the surface area for gas exchange, maximizing partial pressure gradients across those exchange surfaces, ventilating the outer surface with the respiratory medium, and perfusing the inner surface with blood.
- Insects distribute air throughout their bodies in a system of **tracheae, tracheoles**, and air capillaries. **Review Figure 49.4**
- The **gills** of fishes have large gas exchange surface areas that are ventilated continuously and unidirectionally with water. The **countercurrent flow** of blood helps increase the efficiency of gas exchange. **Review Figures 49.5 and 49.6**

- The gas exchange system of birds includes **air sacs** that communicate with the lungs but are not used for gas exchange. Air flows unidirectionally through bird lungs; gases are exchanged in air capillaries that run between **parabronchi**. **Review Figure 49.7**
- Each breath of air remains in a bird's respiratory system for two breathing cycles. The air sacs work as bellows to supply the air capillaries with a continuous unidirectional flow of fresh air. **Review Figure 49.8, ANIMATED TUTORIAL 49.1**
- In all air-breathing vertebrates except birds, breathing is **tidal**. This is a less efficient form of gas exchange than that of fishes and birds. Although the volume of air exchanged with each breath can vary considerably in tidal breathing, the inhaled air is always mixed with stale air. **Review Figure 49.9**

49.3 How Do Human Lungs Work?

- In mammalian lungs, the gas exchange surface area provided by the millions of **alveoli** is enormous, and the diffusion path length between the air and perfusing blood is short. **Surface tension** in the alveoli would make inflation of the lungs difficult if the alveoli did not produce **surfactant**. **Review Figure 49.10, WEB ACTIVITY 49.1**
- Inhalation occurs when contractions of the **diaphragm** pull on the **pleural membranes** and reduce the pressure in the **thoracic cavity**. Relaxation of the diaphragm increases pressure in the thoracic cavity and results in exhalation. **Review Figure 49.11, ANIMATED TUTORIAL 49.2**
- During periods of heavy metabolic demands such as strenuous exercise, the **intercostal muscles**, located between the ribs, increase the volume of air inhaled and exhaled.

49.4 How Does Blood Transport Respiratory Gases?

- O₂ is reversibly bound to **hemoglobin** in red blood cells. Each hemoglobin molecule can carry a maximum of four O₂ molecules. Because of **positive cooperativity**, hemoglobin's affinity for O₂ depends on the P_{O₂} to which the hemoglobin is exposed. Therefore, hemoglobin picks up O₂ as it flows through respiratory exchange structures and gives up O₂ in metabolically active tissues. **Review Figure 49.12**
- Myoglobin serves as an O₂ reserve in muscle.
- There is more than one type of hemoglobin. Fetal hemoglobin has a higher affinity for O₂ than does maternal hemoglobin, allowing fetal blood to pick up O₂ from the maternal blood in the placenta. **Review Figure 49.13, WEB ACTIVITY 49.2**
- CO₂ is transported in the blood principally as **bicarbonate ions** (HCO₃⁻). **Review Figure 49.14**

49.5 How Is Breathing Regulated?

- The breathing rhythm is an autonomic function generated by neurons in the medulla and modulated by higher brain centers. The most important feedback stimulus for breathing is the level of CO₂ in the blood. **Review Figures 49.16 and 14.17**
- The breathing rhythm is sensitive to feedback from chemoreceptors on the ventral surface of the medulla and in the **carotid** and **aortic bodies** on the large vessels leaving the heart. **Review Figure 49.18**

SEE WEB ACTIVITY 49.3 for a concept review of this chapter.

SELF-QUIZ

- Which of the following statements is *not* true?
 - Respiratory gases are exchanged only by diffusion.
 - O₂ has a lower rate of diffusion in water than in air.
 - The O₂ content of water falls as the temperature of water rises.
 - The amount of O₂ in the atmosphere decreases with increasing altitude.
 - Birds have evolved active transport mechanisms to augment their respiratory gas exchange.
- Which statement about the gas exchange system of birds is *not* true?
 - Respiratory gases are not exchanged in the air sacs.
 - A bird can achieve more complete exchange of O₂ from air to blood than humans can.
 - Air passes through birds' lungs in only one direction.
 - The gas exchange surfaces in bird lungs are the alveoli.
 - A breath of air remains in the system for two breathing cycles.
- Which statement about gas exchange in fish is *true*?
 - Blood flows over the gas exchange surfaces in a direction opposite to the flow of water.
 - Gases are exchanged across the gill arches.
 - Ventilation of the gills is tidal in fast-swimming fishes.
 - Less work is needed to ventilate gills in warm water than in cold water.
 - The path length for diffusion of respiratory gases is determined by the length of the gill filaments.
- In the human gas exchange system,
 - the lungs and airways are completely collapsed after a forceful exhalation.
 - the average P_{O₂} concentration of air inside the lungs is always lower than that in the air outside the lungs.
 - the P_{O₂} of the blood leaving the lungs is greater than that of the exhaled air.
 - the amount of air that is moved per breath during normal, at-rest breathing is termed the total lung capacity.
 - O₂ and CO₂ are actively transported across the alveolar and capillary membranes.
- Which statement about the human gas exchange system is *not* true?
 - During inhalation, a negative pressure exists in the space between the lung and the thoracic wall.
 - Smoking one cigarette can immobilize the cilia lining the airways for hours.
 - The respiratory control center in the medulla responds more strongly to changes in arterial O₂ concentration than to changes in arterial CO₂ concentration.
 - Without surfactant, the work of breathing is greatly increased.
 - The diaphragm contracts during inhalation and relaxes during exhalation.

6. The hemoglobin of a human fetus
 - a. is the same as that of an adult.
 - b. has a higher affinity for O_2 than adult hemoglobin has.
 - c. has only two protein subunits instead of four.
 - d. is supplied by the mother's red blood cells.
 - e. has a higher affinity for BPG than adult hemoglobin has.
7. The amount of O_2 carried by hemoglobin depends on the P_{O_2} in the blood. Hemoglobin in active muscles
 - a. becomes saturated with O_2 .
 - b. takes up only a small amount of O_2 .
 - c. readily unloads O_2 .
 - d. tends to decrease the P_{O_2} in the muscle tissues.
 - e. is denatured.
8. Most CO_2 in the blood is carried
 - a. in the cytoplasm of red blood cells.
 - b. as CO_2 dissolved in the plasma.
 - c. in the plasma as bicarbonate ions.
 - d. bound to plasma proteins.
 - e. in red blood cells bound to hemoglobin.
9. Myoglobin
 - a. binds O_2 at P_{O_2} values at which hemoglobin is releasing its bound O_2 .
 - b. has a lower affinity for O_2 than hemoglobin does.
 - c. consists of four polypeptide chains, just as hemoglobin does.
 - d. provides an immediate source of O_2 for muscle cells at the onset of activity.
 - e. can bind four O_2 molecules at once.
10. When the level of CO_2 in the bloodstream increases,
 - a. the rate of respiration decreases.
 - b. the pH of the blood rises.
 - c. the respiratory centers become dormant.
 - d. the rate of respiration increases.
 - e. the blood becomes more alkaline.

FOR DISCUSSION

1. The blood of a certain species of fish that lives in Antarctica has no hemoglobin. What anatomical and behavioral characteristics would you expect to find in this fish, and why is its distribution limited to the waters of Antarctica?
2. Blood banks store whole blood for a much shorter period than they store blood plasma. This is because when blood that has been stored for too long is infused into a patient, it can actually decrease the O_2 available to the patient's tissues. Why is this so? Explain in terms of the different physiological functions of BPG.
3. In 1875 three French physiologists went up in a hot air balloon called Zenith to see the effects of reduced air pressure on breathing. As they went higher and higher, their writing became more illegible and nonsensical, but they did not record any sense of danger. They continued to throw out ballast until they all were unconscious. When the balloon returned to the surface, only one of the scientists recovered; the other two were dead. From your knowledge of respiratory gas exchange and regulation of respiration, how would you explain this tragic episode? Why do you think the three men continued tossing out ballast to ascend higher and higher, without realizing they were in mortal danger of asphyxiation?
4. In patients who have emphysema, the fine structures of alveoli break down, resulting in the formation of larger air cavities in the lungs. Also, the lung tissue becomes less elastic. Give at least two explanations for why such patients have a low tolerance for exercise.
5. A condition called "the bends" affects scuba divers who surface too quickly after spending an extended period in deep water, where they have been breathing pressurized air. The cause of the bends is tiny bubbles of nitrogen coming out of solution in the blood plasma. Seals spend much more time under water and at deeper depths than scuba divers, yet they do not suffer the bends. Why?

ADDITIONAL INVESTIGATION

When you suddenly travel to a location at high altitude, you notice an unusual breathing pattern when you are resting. For a while you stop breathing completely; then suddenly you start breathing rapidly for a short time; then you stop breathing again.

This can go on and on in a cyclical pattern called Cheyne-Stokes breathing. It generally goes away after spending a few days at altitude. Can you hypothesize what causes Cheyne-Stokes breathing and design an experiment to test your hypothesis?

WORKING WITH DATA (GO TO yourBioPortal.com)

Describing Air Flow in Bird Lungs The path of avian air flow described in Figure 49.8 was established in experiments by Bretz and Schmidt-Nielsen at Duke University. This exercise presents their methods and data, along with questions to be considered in light of their results.

Calculating the Functional Residual Volume A spirometer is used to measure volumes of air exchanged during breathing (see Figure 49.9), but a spirometer cannot measure directly the

"dead space," or *residual volume*, of the lungs. The residual volume influences the degree to which incoming fresh air is diluted by the stale air not expelled by the lungs during exhalation. A technique called the *helium dilution method* is used to measure residual volume. In this exercise, you will use data from a helium dilution experiment to calculate the functional residual volume (FRV) of a subject. You will also determine the effect of an increase in FRV on the maximum P_{O_2} in the alveoli.

You gotta have heart

On April 29, 1993, the Boston Celtics met the Charlotte Hornets in a National Basketball Association playoff game at the Boston Garden. The Celtics captain and star, 27-year-old Reggie Lewis, had just scored 10 points in 3 minutes when he suddenly slumped forward and fell to the floor. He was examined by the team doctor, who allowed him to return to the game. But Lewis's legs were "wobbly," and he played only briefly.

Lewis had been experiencing dizzy spells for about a month before the playoff incident. Afterward he under-

went rigorous testing by cardiologists, who diagnosed him as having a dangerous arrhythmia (irregular heartbeat) caused by cardiomyopathy (diseased cardiac muscle). Accepting this diagnosis would mean the end of his professional athletic career, and Lewis sought a second opinion.

After another battery of tests, a second medical team concluded that Lewis had undergone a transient irregular heartbeat attributable to normal athletic stresses. The condition was thought to be due to Lewis's enlarged heart—a condition common in high-performing athletes. In July 1993, after an hour spent shooting baskets in a pick-up game, Reggie Lewis collapsed and died of heart failure.

Your heart is a muscular pump that, at rest, beats an average of 60 to 70 times per minute. With each beat, it circulates about 70 milliliters of blood through the body. Without taking work or exercise into account, that is 300 liters per hour, 7,200 liters per day, 2.6 million liters per year—no time-outs.

Heart failure is the leading cause of death in the United States, accounting for some one-fourth (about 600,000) of the deaths each year. Heart failure most commonly results from blockage of the vessels that supply the heart muscle with blood, and its risk increases with age. But heart failure is also the leading cause of death among young athletes.

In athletes, heart failure is usually due not to vessel blockage but to defects of the heart or blood vessels. The most common defect is hypertrophic cardiomyopathy (HCM), caused by a mutation that affects the contractile proteins of heart muscle. The heart is good at compensating for these mutant proteins. About 0.5 percent of the population has HCM, and most of them are unaware of it; they can live their entire lives without symptoms. With

An Athlete's Heart Basketball star Reggie Lewis died of heart failure at the age of 27. The exact medical situation underlying his heart problems remains clouded in controversy.

Clear! Hospital emergency rooms deal with heart attacks on a daily basis. Advances in heart surgery and emergency resuscitation techniques have saved many lives, but circulatory system failure remains the number one cause of death in Europe, Canada, and the United States.

continued heavy exercise, however, the heart compensates by getting larger. Eventually, this increase in size can disrupt the electrical impulses that coordinate contractions of the heart muscle. When heavy demand is placed on such an enlarged heart, muscle fiber contractions can suddenly become uncoordinated and render the heart incapable of pumping blood. The lack of prior symptoms is why the condition often goes undiagnosed.

Diagnosis is getting better. In December 2008, 33-year-old Cuttino Mobley, who had just joined the New York Knicks, announced his retirement from basketball after learning that his career could kill him. Like Reggie Lewis, Mobley has an enlarged heart. When a physical exam showed arrhythmia, Mobley's physician ordered an MRI that revealed the thickening of the heart walls characteristic of HCM. "Getting the MRI saved my life," Mobley said.

IN THIS CHAPTER we will learn about the adaptations of circulatory systems that enable them to match blood supply with demand in a variety of species. Taking the human circulatory system as a model, we will explore the mechanics of the beating heart and the characteristics of the arteries, capillaries, and veins of the vascular system. We will then describe the features of blood before ending with a discussion of the hormonal and neural regulation of the mammalian circulatory system.

CHAPTER OUTLINE

- 50.1** Why Do Animals Need a Circulatory System?
- 50.2** How Have Vertebrate Circulatory Systems Evolved?
- 50.3** How Does the Mammalian Heart Function?
- 50.4** What Are the Properties of Blood and Blood Vessels?
- 50.5** How Is the Circulatory System Controlled and Regulated?

50.1 Why Do Animals Need a Circulatory System?

A **circulatory system** consists of a muscular pump (the heart), a fluid (blood), and a series of conduits (blood vessels) through which the fluid can be pumped around the body. Heart, blood, and vessels are also known collectively as a **cardiovascular system** (Greek *kardia*, "heart," and Latin *vasculum*, "vessel"). The function of a circulatory system is to transport things around the body. Preceding chapters discuss how circulatory systems transport heat, hormones, respiratory gases, blood cells, platelets, and cells and molecules of the immune system. Succeeding chapters add nutrients and waste products to that list. In this section we will describe the general types of circulatory systems found in animals.

Some animals do not have a circulatory system

Single-celled organisms serve all of their needs through direct exchanges with the environment. Such organisms are found mostly in aquatic or very moist terrestrial environments. Similarly, many multicellular aquatic organisms are small or thin enough that all their cells are close to the external environment. Such species may not have a circulatory system because nutrients, respiratory gases, and wastes can diffuse directly between the cells of their bodies and the environment.

The cells of some larger aquatic multicellular animals without a circulatory system are served by highly branched central cavities called *gastrovascular systems* which essentially bring the external environment into the animal. All the cells of a sponge, for example, are in contact with, or very close to, the water that surrounds the animal and circulates through its central cavity (see Figure 49.1B). Very small animals without a circulatory system can maintain high levels of metabolism and activity, but larger animals without a circulatory system such as sponges, jellyfishes, and flatworms tend to be inactive, slow, or even sedentary. Large, active animals need a circulatory system.

Circulatory systems can be open or closed

The cells of large, mobile animals are supported by the extracellular fluid. All nutrients—oxygen, fuel, essential molecules—come from that fluid, and the waste products of cell metabolism go into it. Circulatory systems have muscular chambers, or *hearts*, that move the extracellular fluid around the body. In *open circulatory systems*, extracellular fluid is the same as the fluid in the

circulatory system and is called *hemolymph*. This fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the heart or vessels of the circulatory system to be pumped out again. In contrast, *closed circulatory systems* completely contain the circulating fluid (*blood*) in a continuous system of vessels. Blood cells and large molecules stay within the system, but water and low-molecular-weight solutes leak out of the smallest vessels, the *capillaries*, which are highly permeable.

In animals with a closed circulatory system, *extracellular fluid* refers to both the fluid in the circulatory system and the fluid outside it. The fluid in the circulatory system is the *blood plasma*; the fluid around the cells is the *interstitial fluid* (see Figure 40.1). A 70-kilogram person has a total extracellular fluid volume of about 14 liters. Less than a quarter of it—about 3 liters—is the blood plasma.

Circulatory systems control the distribution of blood to the body's tissues and organs, with two reciprocal and complementary functions: to maintain the blood composition by picking up nutrients and eliminating wastes, and to supply nutrients to and remove wastes from the body's tissues.

Open circulatory systems move extracellular fluid

Open circulatory systems are found in arthropods, mollusks, and some other invertebrate groups. In these systems, a muscular pump, or heart, helps move the hemolymph through vessels leading to different regions of the body. The fluid leaves the vessels to trickle through the tissues before returning to the heart. In the generalized arthropod shown in **Figure 50.1A**, the fluid returns directly to the heart through openings called *ostia*. Ostia have valves that allow hemolymph to enter the relaxed heart but prevent it from flowing in the reverse direction when the heart contracts. In mollusks (**Figure 50.1B**), open vessels collect hemolymph from different regions of the body and return it to the heart.

Closed circulatory systems circulate blood through a system of blood vessels

In **closed circulatory systems**, a system of vessels keeps circulating blood separate from the interstitial fluid. Blood is pumped through this *vascular system* by one or more muscular hearts, and some components of the blood never leave the vessels. Closed circulatory systems characterize vertebrates and some invertebrate groups, among them annelids.

A simple example of a closed circulatory system is that of the earthworm (**Figure 50.1C**). One large ventral blood vessel carries blood from the worm's anterior end to its posterior end. Smaller vessels branch off and transport the blood to even smaller vessels serving the tissues in each body segment. In the smallest vessels, respiratory gases, nutrients, and metabolic wastes diffuse between the blood and interstitial fluid. The blood then flows from these vessels into larger vessels that lead into one large dorsal vessel, which carries the blood from the posterior to the anterior end of the body. Five pairs of muscular vessels connect the large dorsal and ventral vessels in the anterior end, thus completing the circuit. The dorsal vessel and

(A) Arthropod

(B) Mollusk

(C) Annelid worm

50.1 Circulatory Systems Arthropods, illustrated here by an insect (A), and mollusks such as clams (B) have an open circulatory system. Hemolymph is pumped by a tubular heart and directed to different regions of the body through vessels that open into intercellular spaces. (C) Annelids such as earthworms have a closed circulatory system, in which the cellular and macromolecular elements of the blood are confined in a system of vessels and the blood is pumped through those vessels by one or more muscular hearts.

the five connecting vessels serve as hearts for the earthworm; their contractions keep the blood circulating. The direction of circulation is determined by one-way valves in the dorsal and connecting vessels.

Closed circulatory systems have several advantages over open systems:

- Fluid can flow more rapidly through vessels than through intercellular spaces and can therefore transport nutrients and wastes to and from tissues more rapidly.
- By changing the diameter (hence resistance) of specific vessels, closed systems can control the flow of blood to selective tissues and organs to match their needs.
- Specialized cells and large molecules that aid in transporting hormones and nutrients can be kept in the vessels but can drop their cargo in the tissues where it is needed.

It seems logical to accept the premise that in all but very small animals, closed circulatory systems can support higher levels of metabolic activity than open systems can. But we then have to ask: How do highly active insect species achieve high levels of metabolic output with an open circulatory system? The reason is that insects do not depend on their circulatory systems for respiratory gas exchange. As noted in Chapter 49, respiratory gas exchange in insects is through a separate system of air-filled tubes (see Figure 49.4).

50.1 RECAP

Circulatory systems consist of a pump and an open or closed set of vessels through which a fluid transports oxygen, nutrients, wastes, and a variety of other substances.

- Why are most animals with an open circulatory system rather inactive, and why does that not apply to insects? **See p. 1047 and Figure 50.1**
- What are some advantages of a closed circulatory system? **See p. 1048**

This overview of the open and closed systems of invertebrates introduced some basic concepts about circulatory systems. Now let's turn to describing the more complex circulatory systems of vertebrates.

50.2 How Have Vertebrate Circulatory Systems Evolved?

Vertebrates have a closed circulatory system and a heart with two or more chambers. When a heart chamber contracts, it squeezes the blood, putting it under pressure. Blood then flows out of the heart and into vessels, where pressure is lower. Valves prevent the backflow of blood as the heart cycles between contraction and relaxation.

As we explore the features of the circulatory systems of different classes of vertebrates, a general evolutionary theme will emerge: as circulatory systems become more complex, the blood that flows to the gas exchange organs (gills or lungs; see Chapter 49) becomes more completely separated from the blood that flows to the rest of the body.

In fishes, the phylogenetically oldest vertebrates, blood is pumped from the heart to the gills and then to the tissues of the body and back to the heart—a single circuit. In birds and mammals, blood is pumped from the heart to the lungs and back to the heart in a **pulmonary circuit**, and then from the heart to the rest of the body and back to the heart in a **systemic circuit**. In all other vertebrates we see various adaptations for separating the blood flow into pulmonary and systemic circuits.

Both pulmonary and systemic circuits begin with vessels called **arteries** that carry blood away from the heart. Arteries give rise to smaller vessels called **arterioles**, which feed blood into *capillary beds*. **Capillaries** are the tiny, thin-walled vessels where materials are exchanged between the blood and the tissue fluid. Small vessels called **venules** drain capillary beds. The venules join to form larger vessels called **veins**, which deliver blood back to the heart.

We can trace the evolutionary history of vertebrate circulatory systems by comparing the circulatory systems of fishes, lungfishes, amphibians, ectothermic reptiles, and birds and mammals.

Fishes have a two-chambered heart

The fish heart has two chambers. An **atrium** (plural *atria*) receives blood from the body and pumps it into a more muscular chamber, the **ventricle**. The ventricle pumps the blood to the gills, where gases are exchanged. Blood leaving the gills collects in a large dorsal artery, the **aorta**, which distributes blood to smaller arteries and arterioles leading to all the organs and tissues of the body. In the tissues, blood flows through beds of tiny capillaries, collects in venules and veins, and eventually returns to the atrium of the heart.

Most of the pressure imparted to the blood by the contraction of the ventricle is lost as a result of the blood entering the many narrow spaces in the gill lamellae. Therefore, blood leaving the gills and entering the aorta is under low pressure, limiting the maximum capacity of the fish circulatory system to supply the tissues with oxygen and nutrients. Yet this limitation on arterial blood pressure does not seem to hamper the performance of many rapidly swimming species, such as tuna and marlin.

The evolutionary transition from breathing water to breathing air had important consequences for the vertebrate circulatory system. An example of how the system changed to serve a primitive lung can be seen in the African lungfish.

Lungfish are periodically exposed to water with low oxygen content or to situations in which their aquatic environment dries up. The adaptation that deals with these conditions is an out-pocketing of the gut that serves as a lung. The lung contains many thin-walled blood vessels, so blood flowing through those vessels can pick up oxygen from air gulped into the lung.

How does the lungfish circulatory system take advantage of this new organ? In fishes, the gills are arranged on supportive gill arches (see Figure 49.5). Blood flows into the gill arch in an afferent arteriole and leaves in an efferent arteriole. In lungfishes, the blood vessels in the posterior pair of gill arteries have been modified to be a low-resistance conduit for blood to the lung, and a new vessel carries oxygenated blood from the lung back to the heart. In addition, two anterior gill arches have lost their gills, and their blood vessels deliver blood from the heart directly to the dorsal aorta. Because a few of the gill arches retain gills, the African lungfish can breathe either air or water.

The lungfish heart partially separates its flow of blood into pulmonary and systemic circuits; it has a partially divided atrium. The left side receives oxygenated blood from the lungs, and the right side receives deoxygenated blood from the other tissues. These two bloodstreams stay mostly separate as they flow through the ventricle and the large vessel leading to the gill arches. As a result, oxygenated blood goes mostly to the anterior gill arteries leading to the dorsal aorta, and deoxygenated blood goes mostly to the other gill arches that have functional gills as well as to the gill arteries that serve the lung.

We can conclude that the lungfish lung evolved as a means of supplementing oxygen uptake from the gills. When the water is fully oxygenated, the lungfish can depend on its gills; but in oxygen-depleted water, it can augment its oxygen intake by gulping air. Associated modifications of the lungfish vascular system set the stage for the evolution of separate pulmonary and systemic circulations in higher vertebrates.

Amphibians have a three-chambered heart

Pulmonary and systemic circulations are partially separated in adult amphibians. A single ventricle pumps blood to the lungs and the rest of the body. Two atria receive blood returning to the heart: one receives oxygenated blood from the lungs, while the other receives deoxygenated blood from the body.

Because both atria deliver blood to the same ventricle, the oxygenated and deoxygenated blood could mix, so that blood going to the tissues would not carry a full load of oxygen. Mixing is limited, however, because anatomical features of the ventricle direct the flow of deoxygenated blood from the right atrium to the pulmonary circuit and the flow of oxygenated blood from the left atrium to the aorta. Partial separation of pulmonary and systemic circulation has the advantage of allowing blood destined for the tissues to sidestep the large pressure drop that occurs in the gas exchange organ. Blood leaving the amphibian heart for the tissues moves directly to the aorta, and hence to the body, at a higher pressure than if it had first flowed through the lungs.

Amphibians have another adaptation for oxygenating their blood: they can pick up a considerable amount of oxygen in blood flowing through small blood vessels in their skin.

Reptiles have exquisite control of pulmonary and systemic circulation

Reptiles include turtles, snakes, lizards, crocodilians, and birds (see Figure 33.18). Crocodilians and birds have cardiovascular systems with two completely separated ventricles, creating a four-chambered heart. All other reptiles have a three-chambered heart because their ventricles are not completely separated into left and right chambers.

Consider the behavior, ecology, and physiology of *ectothermic* reptiles. Many are active, powerful, fast animals. But their activity comes in bursts that are interspersed with long periods of inactivity, during which these animals' metabolic rates are much lower than the resting metabolic rates of the *endothermic* birds and mammals. So enormous is the range of metabolic demand in ectothermic reptiles that they do not need to breathe continuously. Some species are accomplished divers and spend long periods under water, where they cannot breathe air.

When these animals are not breathing, it would be a waste of energy for them to pump blood through their lungs. Thus, they have evolved the capability to send blood to the lungs and the rest of the body when they are breathing, but when they are

not breathing, they can bypass the pulmonary circuit and pump all the blood to the body. How do they do this?

Let's look first at the ectothermic reptiles with a three-chambered heart—the turtles, snakes, and lizards. The ventricle in these species is partially divided into left and right halves by a septum. Oxygenated blood from the lungs enters the left side of the ventricle through the left atrium. Deoxygenated blood from the body enters the right side of the ventricle through the right atrium. These species have two aortas—a left and a right. The left aorta is positioned so that it receives oxygenated blood from the left side of the ventricle. The right aorta, however, is positioned so that it can receive blood from either the right or left side of the ventricle.

When the animal is breathing air, the resistance in the pulmonary circuit is lower than the resistance in the systemic circuit, so blood from the right side of the ventricle tends to flow into the pulmonary artery rather than the right aorta. When the animal is not breathing, pulmonary vessels constrict, resistance in the pulmonary circuit goes up, and blood from the right side of the ventricle tends to flow into the right aorta. As a result, blood from both sides of the ventricle flows through both aortas to the systemic circuit.

Crocodilians, like birds, have two completely separated ventricles. Unlike birds, they have two aortas, one originating in each ventricle. There is a connection between the two aortas just

as they leave the heart, and this connection enables them to alter the proportions of blood going to their pulmonary and systemic circuits. When a crocodile or alligator is breathing and resistance in the pulmonary circuit is low, backpressure from the stronger left ventricle closes the valve between the right ventricle and the right aorta, forcing all of the blood from the right ventricle to flow into the pulmonary circuit. When the animal stops breathing, pulmonary vessels constrict, resistance in the pulmonary circuit rises, and blood from the right ventricle flows into the right aorta. This ability of all ectothermic reptiles to direct blood to their pulmonary or systemic circuits is highly adaptive for their lifestyle of intermittent breathing.

Birds and mammals have fully separated pulmonary and systemic circuits

The four-chambered hearts of birds and mammals have completely separate pulmonary and systemic circuits. Separate circuits have several advantages for these active animals with continuously high metabolic rates:

- Oxygenated and deoxygenated blood cannot mix; therefore, the systemic circuit always receives blood with the highest oxygen content.
- Respiratory gas exchange is maximized because the blood with the lowest oxygen content and highest CO_2 content is sent to the lungs.
- Separate systemic and pulmonary circuits can operate at different pressures.

The tissues of birds and mammals have high nutrient demands and thus a very high density of blood vessels, requiring the heart to generate a high blood pressure to perfuse all the vessels of the systemic circuit. The pulmonary circuit of these animals receives a blood flow equal to that of the systemic circuit, but the lungs have far fewer blood vessels. Thus, the pulmonary circuit of birds and mammals can function at lower pressures, and the four-chambered heart makes that possible.

50.2 RECAP

The closed circulatory system of vertebrates has evolved from a two-chambered heart in fishes to a four-chambered heart in crocodilians, birds, and mammals.

- Explain why fishes cannot supply blood to their tissues at high pressure. **See p. 1048**
- By comparing lungfish and amphibian circulatory systems, explain how a three-chambered heart could have evolved. **See pp. 1048–1049**
- What are some of advantages of a four-chambered heart? **See p. 1050**

50.3 How Does the Mammalian Heart Function?

Humans have a typical mammalian heart, characterized by four chambers—a right and a left atrium and a right and a left ventricle (**Figure 50.2**). The right ventricle pumps blood through the pulmonary circuit, and the left ventricle pumps blood through the systemic circuit.

One-way valves between the atria and ventricles, the **atrioventricular (AV) valves**, prevent backflow of blood into the atria when the ventricles contract. The **pulmonary valve** and **aortic valve**, one-way valves between the ventricles and the major arteries, prevent backflow of blood into the ventricles when they relax.

In this section, we will describe the flow of blood through the heart and body and examine the unique electrical properties of cardiac muscle that result in the heartbeat.

Blood flows from right heart to lungs to left heart to body

The heart's right atrium receives deoxygenated blood from the **superior** (upper) **vena cava** and the **inferior** (lower) **vena cava** (see Figure 50.2), large veins that collect blood returning to the

heart from the upper and lower body, respectively. The veins of the heart itself also drain into the right atrium. From the right atrium, the blood flows through an AV valve into the right ventricle. Most of the filling of the ventricle results from passive flow while the heart is relaxed between beats. Just at the end of this period of passive ventricular filling, the atrium contracts and adds a little more blood to the ventricular volume. The right ventricle then contracts, causing the AV valve to close and pumping the blood into the **pulmonary artery** leading to the lungs.

After gas exchange occurs in the lungs, **pulmonary veins** return oxygenated blood from the lungs to the left atrium, from which the blood enters the left ventricle through another AV valve. As on the right side of the heart, most left ventricular filling is passive, but ventricular filling is completed when the atria contract.

The walls of the left ventricle are powerful muscles that contract around the blood with a wringing motion starting from the bottom. When pressure in the left ventricle is high enough to push open the aortic valve, blood rushes into the aorta to begin its circulation throughout the body. In Figure 50.2, observe that the walls of the left ventricle are thicker than those of the right ventricle. The left ventricle has to propel blood through many more kilometers of blood vessels than does the right ven-

tricle, and must therefore push against more resistance, even though both ventricles pump the same volume of blood.

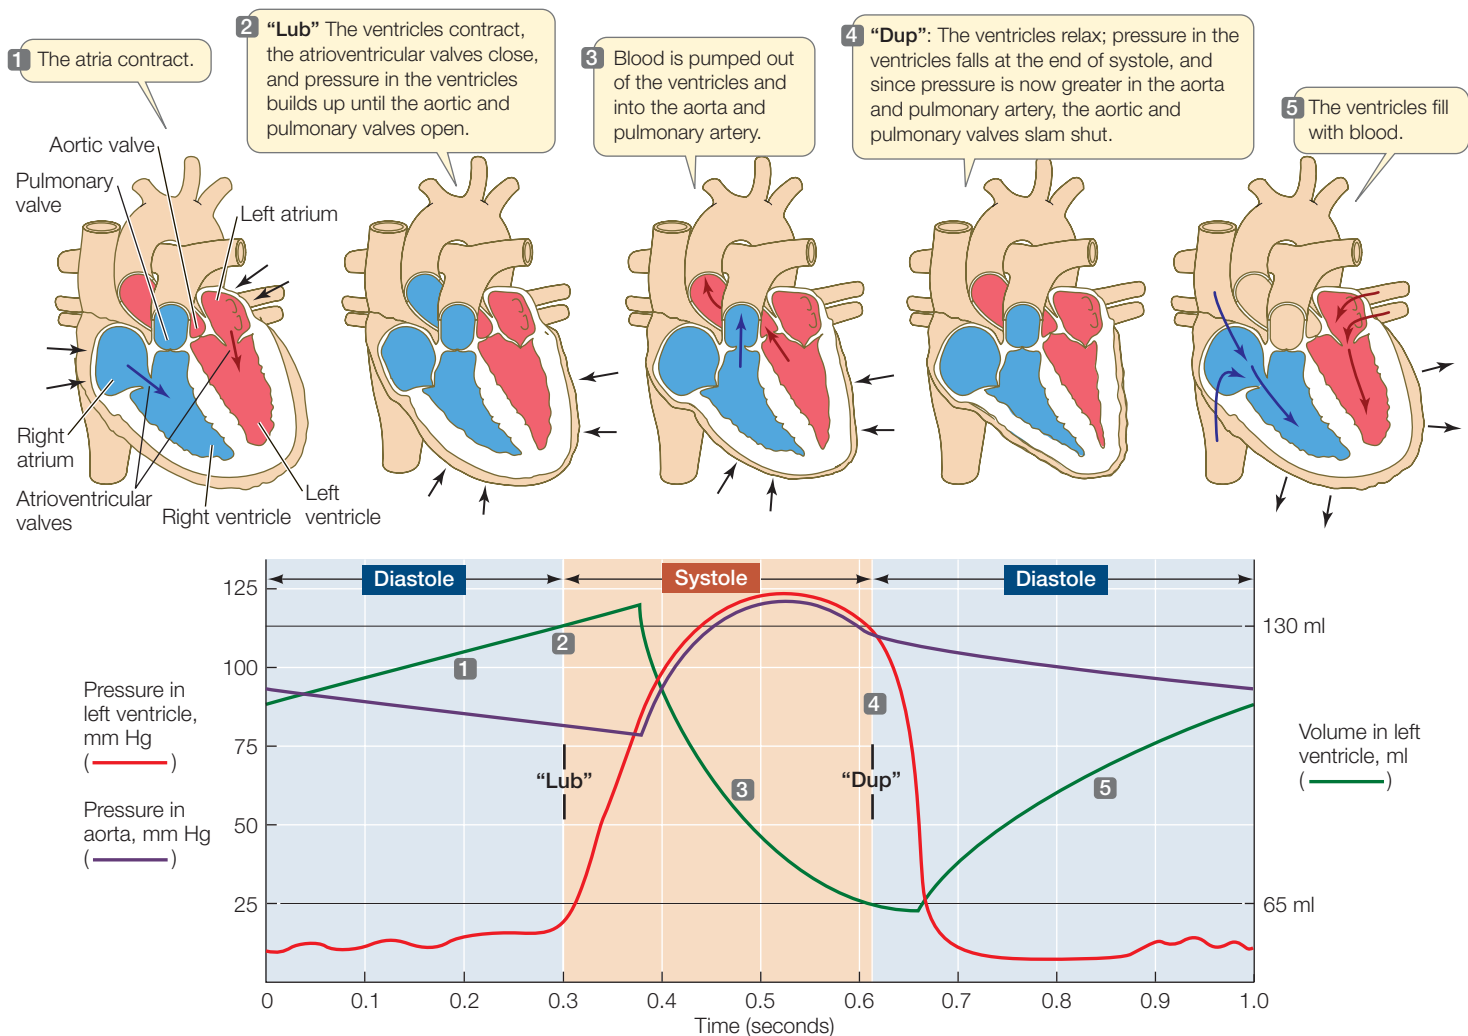

Both sides of the heart contract at the same time. Contraction of the two atria, followed by contraction of the two ventricles and then relaxation, is the **cardiac cycle**. The cardiac cycle is divided into two phases: **systole** (pronounced *sís-toll-ee*), when the ventricles contract, and **diastole** (*die-ás-toll-ee*), when the ventricles relax (Figure 50.3). Just at the end of diastole, the atria contract and top off the volume of blood in the ventricles.

The sounds of the cardiac cycle, the “lub-dup” heard through a stethoscope placed on the chest or the back, are created by the heart valves slamming shut. The closing and opening of these valves are simple mechanical events resulting from pressure differences on the two sides of the valves. As the ventricles begin to contract, the pressure in them rises above the pressure in the atria, so the AV valves close (“lub”). When the ventricles be-

50.3 The Cardiac Cycle The rhythmic contraction (systole) and relaxation (diastole) of the ventricles is called the cardiac cycle. The representation below shows pressure and volume changes during the cardiac cycle for the left ventricle only.

gin to relax, the high pressure in the aorta and pulmonary artery closes the aortic and pulmonary valves (“dup”).

Defective valves that do not close completely produce turbulent blood flow and the sounds known as *heart murmurs*. For example, if an AV valve does not close completely, blood will flow back into the atrium with a “whoosh” following the “lub.”

You can feel the rhythm of the cardiac cycle in the pulsation of arteries such as the one that supplies blood to your hand. You’ve probably taken your pulse by placing two fingers from one hand lightly over the wrist of your other hand just below the thumb. During systole, the pressure wave created by the contraction of the left ventricle surges through the arteries of your arms; this pressure wave is what you feel as the pulsing of the artery in your wrist.

Blood pressure changes associated with the cardiac cycle can be measured in the large artery in your arm by using an inflatable pressure cuff and a pressure gauge, together called a *sphygmomanometer*, and a stethoscope (**Figure 50.4**). This method measures the minimum pressure necessary to compress an artery so blood does not flow through it at all (the systolic value) and the minimum pressure that causes intermittent flow through the artery (the diastolic value). A conventional blood pressure reading is expressed as the systolic value placed over the diastolic value. Healthy values for a young adult might be 120 millimeters of mercury (mm Hg) during systole and 70 mm Hg during diastole, or 120/70.

The heartbeat originates in the cardiac muscle

Cardiac muscle (see Section 48.1) has unique adaptations that enable it to function as a pump. First, cardiac muscle cells are in electrical contact with one another through gap junctions,

which enable *action potentials* (see Section 45.2) to spread rapidly from cell to cell. Because a spreading action potential stimulates contraction, large groups of cardiac muscle cells contract in unison. This coordinated contraction is essential for pumping blood effectively.

Second, some cardiac muscle cells are **pacemaker cells** that can initiate action potentials without stimulation from the nervous system. When they fire action potentials, they stimulate neighboring cells to contract. The primary pacemaker of the heart is a group of modified cardiac muscle cells, the **sinoatrial node**, located at the junction of the superior vena cava and right atrium (see Figure 50.6). The *resting membrane potentials* of these cells are less negative than those of other cardiac muscle cells and are not stable, but they gradually become even less negative until they reach threshold for initiating an action potential. The action potentials of pacemaker cells are very different from those of neurons and other muscle cells (see Figure 45.10). They are slower to rise; they are broader; and they are slower to return to resting potential. These properties of pacemaker cells are due to the ion channels in their membranes.

Pacemaker potentials involve Na^+ , Ca^{2+} , and K^+ channels. As we discuss in Section 45.2, when Na^+ or Ca^{2+} channels open, positive charges flow into the cell and the membrane potential becomes less negative. When K^+ channels open, positive charges flow out of the cell and the membrane potential becomes more negative. Because the Na^+ channels of pacemaker cells are more open than are those of other cardiac muscle cells, the pacemaker resting potential is less negative. The action potential of pacemaker cells is due to voltage-gated Ca^{2+} channels rather than voltage-gated Na^+ channels as in neurons, skeletal muscle, and other cardiac muscle cells. These Ca^{2+} ion channels open and close more slowly than voltage-gated Na^+ channels, explaining the shape of pacemaker action potentials.

The unstable resting potential of pacemaker cells is due to the behavior of cation channels. As in neurons and skeletal muscle cells, there are voltage-gated K^+ channels that open on the rising phase of the action potential. The opening of these channels allows K^+ ions to leave the cell and restores the negative charge on the cell membrane. The hyperpolarization (negative membrane potential) causes the opening of a unique class of voltage-gated cation channels that mostly conduct Na^+ . At the same time, the voltage-gated K^+ channels that opened during the action potential are slowly closing. The result is that there are more Na^+ ions coming into the cell than there are K^+ ions leaving, and the cell membrane potential gradually becomes less negative.

50.4 Measuring Blood Pressure Blood pressure in the major artery of the arm can be measured with a device called a sphygmomanometer, which combines an inflatable cuff and a pressure gauge. A stethoscope is also used to detect sounds created by the blood vessels in response to changes in pressure during the cardiac cycle.

INVESTIGATING LIFE

50.5 The Autonomic Nervous System Controls Heart Rate

The membrane potentials of pacemaker cells spontaneously depolarize until action potential threshold is reached. Neurotransmitter signals from the two divisions of the autonomic nervous system speed up and slow down the rate at which the pacemaker membrane potential drifts upward, thereby controlling the rate at which pacemaker cells fire action potentials.

HYPOTHESIS The autonomic nervous system neurotransmitters norepinephrine and acetylcholine influence the membrane potentials of pacemaker cells.

METHOD

1. Culture living sinoatrial node tissue in a dish. Insert an intracellular recording electrode into pacemaker cells.
2. Measure the membrane potential of pacemaker cells during a resting heartbeat (the control) and after applications of the ANS neurotransmitters norepinephrine (sympathetic) and acetylcholine (parasympathetic).

RESULTS

CONCLUSION The ANS neurotransmitters norepinephrine and ACh control heart rate by altering the properties of the pacemaker cell membrane potentials.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

ffects on membrane potential causes the rhythmic generation of action potentials that characterizes the pacemaker cells.

The nervous system controls the heartbeat (speeds it up or slows it down) by influencing the rate at which the pacemaker cell resting potentials drift upward (**Figure 50.5**). Norepinephrine released onto pacemaker cells by sympathetic nerves increases the permeability of the Na^+ channels and the Ca^{2+} channels. The result is that the resting potential of the pacemaker cells drifts up more rapidly, the interval between action potentials is decreased, and the heart beats faster. Conversely, the parasympathetic neurotransmitter acetylcholine has the opposite effect. ACh increases the permeability of K^+ channels so that the membrane potential becomes even more negative following an action potential and rises more slowly. ACh also decreases the permeability of the Ca^{2+} channels so that the rate of rise of the membrane potential slows, the interval between pacemaker action potentials lengthens, and the heart slows down.

A conduction system coordinates the contraction of heart muscle

A normal heartbeat begins with an action potential in the sinoatrial node (**Figure 50.6**). This action potential spreads rapidly throughout the electrically coupled cells of the atria, causing them to contract in unison. Because there are no gap junctions between the cells of the atria and those of the ventricles, the action potential does not spread directly to the ventricles. Therefore, the ventricles do not contract in unison with the atria.

How does the action potential move from the atria to the ventricles? Situated at the junction of the atria and the ventricles is a nodule of modified cardiac muscle cells—the **atrioventricular node**—which is stimulated by the depolarization of the atria. With a slight delay, it generates action potentials that are conducted to the ventricles via the **bundle of His**, which consists of modified cardiac muscle fibers that do not contract. These fibers divide into right and left *bundle branches* that run to the tips of the ventricles and then spread throughout the ventricular muscle mass as **Purkinje fibers**. These conducting fibers ensure that the cardiac action potential spreads rapidly and evenly throughout the ventricular muscle mass, starting at the very bottom of the ventricles. The short delay in the spread of the action potential imposed by the atrioventricular node ensures that the atria contract before the ventricles do, so that the blood passes progressively from the atria to the ventricles to the arteries.

Electrical properties of ventricular muscles sustain heart contraction

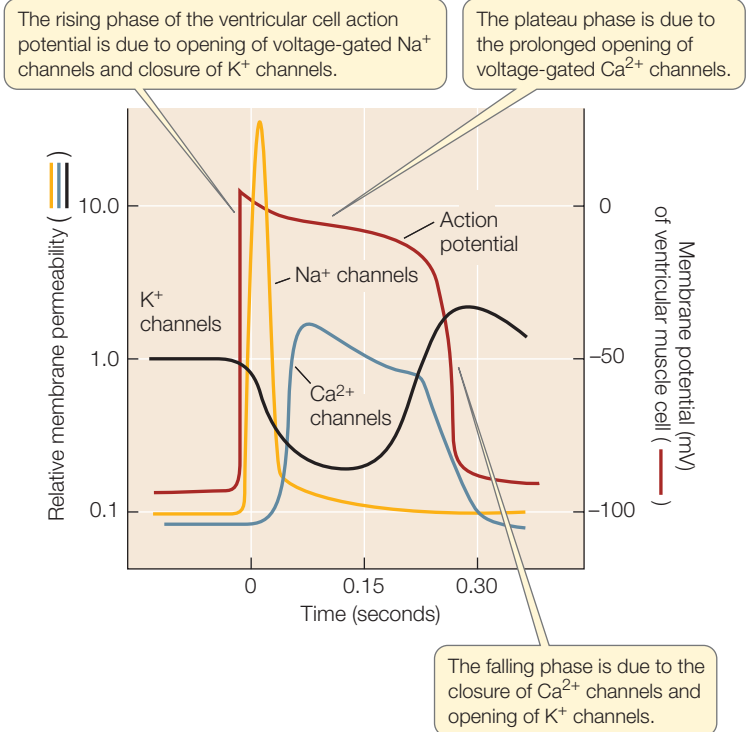

Electrical properties of ventricular muscle fibers allow them to contract for about 300 milliseconds—much longer than those of skeletal muscle fibers. As in neuronal and skeletal muscle

The gradual rise in membrane potential closes the channels that are allowing Na^+ to move into the cell, but as the membrane becomes less negative, some Ca^{2+} channels open, causing the membrane to continue its gradual rise. Eventually this rising membrane potential reaches threshold for the major voltage-gated Ca^{2+} channels, and another action potential is generated. The intricate interaction of these ion channels through their ef-

Heart at rest (diastole)**Atrial contraction****Ventricular contraction (systole)**

50.6 The Heartbeat Pacemaker cells in the sinoatrial node initiate the heartbeat by firing action potentials that spread through the electrically coupled atrial muscle. The atrial action potential eventually spreads to the atrioventricular node that, with a delay, conducts it through the Bundle of His and Purkinje fibers to the cells of the ventricles.

action potentials, the rising phase of the ventricular muscle cell action potentials is due to the opening of voltage-gated Na^+ channels. Unlike neurons and skeletal muscle fibers, however, ventricular muscle cells remain depolarized for a long time. This extended plateau of the action potential is due to sustained opening of voltage-gated Ca^{2+} channels (**Figure 50.7**). Like

50.7 The Action Potential of Ventricular Muscle Fibers The rising phase of the action potential of ventricular muscle fibers (red) is due to the opening of voltage-gated Na^+ channels (gold). However, the membrane remains in a depolarized state for a prolonged time because of the opening of voltage-gated K^+ channels (black).

other muscle, cardiac muscle is stimulated to contract when Ca^{2+} is available to bind with troponin (see Figure 48.6). As long as Ca^{2+} remains in the sarcoplasm, the ventricular muscle cells continue to contract.

The drug digitalis has been used since the late 1700s to treat weakened hearts or hearts with irregular patterns of contraction. Digitalis strengthens and slows the heartbeat by slowing the reuptake of Ca^{2+} by the sarcoplasmic reticulum and thereby increasing the concentration of Ca^{2+} in the sarcoplasm. Before being introduced into the practice of medicine, digitalis prepared from the purple foxglove plant, *Digitalis purpurea*, was a folk remedy for heart problems.

The ECG records the electrical activity of the heart

Electrical events in the cardiac muscle during the cardiac cycle can be recorded by electrodes placed on the surface of the body. Such a recording is an **electrocardiogram**, or **ECG**. **EKG** is also used because German physicians who invented the method used the Greek word for heart and called it the *elektrokardiogramm*. The ECG is an important tool for diagnosing heart problems (**Figure 50.8A**).

The action potentials that sweep through the muscles of the atria and ventricles before they contract are such massive, localized electrical events that they cause electric currents to flow throughout the body. Electrodes placed at different locations on

50.8 The Electrocardiogram (A) An electrocardiogram (abbreviated as ECG or EKG) is used to monitor heart function. Electrodes attached to the person on the treadmill record an ECG that is amplified and displayed on a monitor. (B) Variations from the normal pattern shown here can be used to diagnose heart problems.

the skin detect those currents at different times and register a voltage difference between them. The appearance of the ECG depends on the placement of the electrodes. Electrodes placed on the right wrist and left ankle produced the normal ECG shown in **Figure 50.8B**. The wave patterns of the ECG are designated P, Q, R, S, and T, each letter representing a particular event in the cardiac muscle, as shown in the figure.

50.3 RECAP

The mammalian heart has two atria and two ventricles. Modified cardiac muscle tissue in the right atrium functions to spontaneously generate pacemaker action potentials. Other modified cardiac muscle tissue between the atria and ventricles and throughout the ventricles conducts those signals and coordinates the heart contraction.

- Trace the path of blood through both sides of the heart, naming the major blood vessels and heart valves. **See pp. 1051–1052 and Figure 50.2**
- Differentiate systole and diastole and describe the events of the cardiac cycle. **See p. 1052 and Figure 50.3**
- How do cells of the sinoatrial node generate the heart-beat? **See pp. 1053–1054 and Figures 50.5 and 50.6**

We'll now consider the composition of the blood and the characteristics of the vessels through which blood circulates around the body, illustrating once again how structure serves function. We will also consider the role of the lymphatic vessels that return interstitial fluid to the blood.

50.4 What Are the Properties of Blood and Blood Vessels?

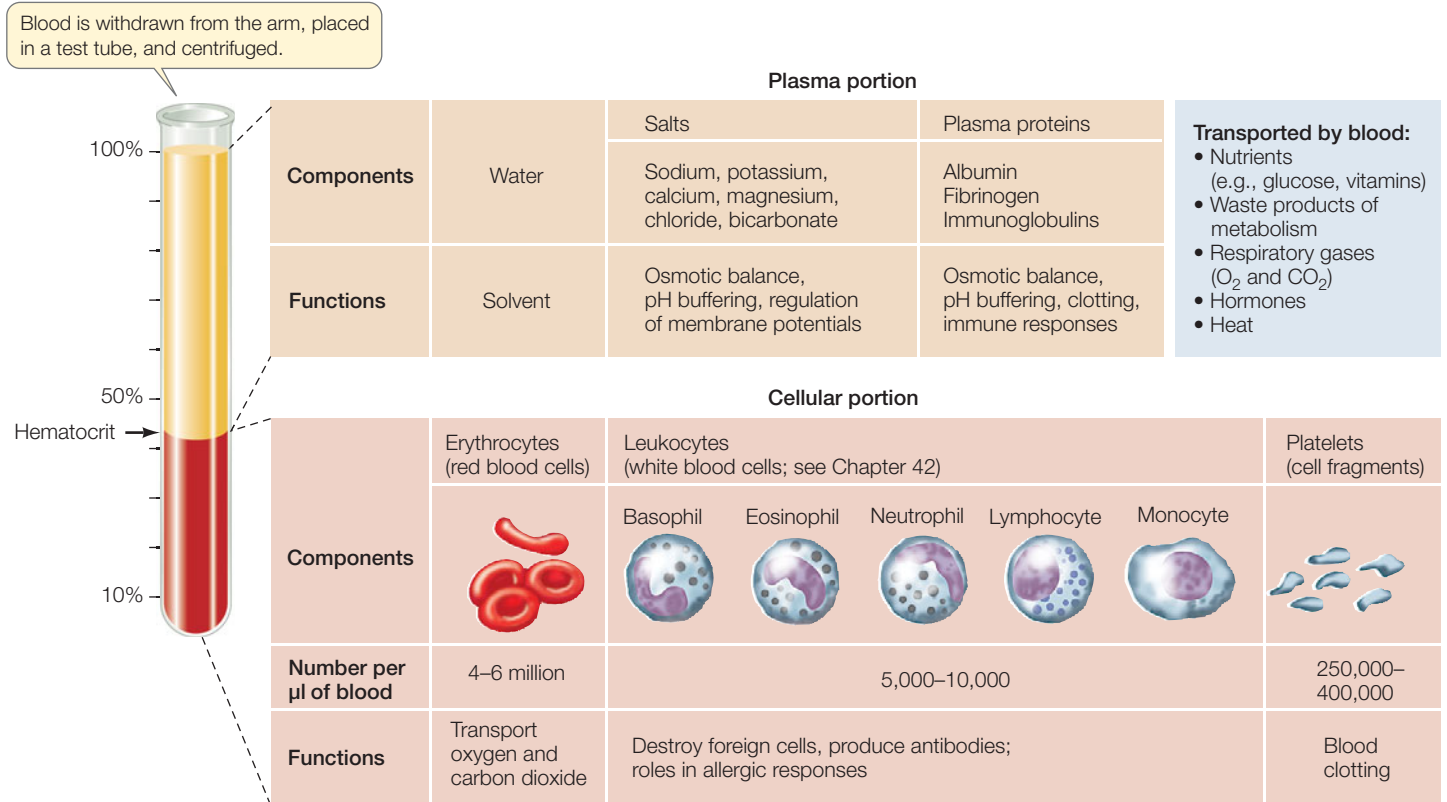

Blood is a connective tissue. It consists of cells suspended in an extracellular matrix of complex, yet specific, composition. The unusual feature of blood is that the extracellular matrix is a liquid, so blood is a fluid tissue.

The cells of the blood can be separated from the fluid matrix, called **plasma**, by centrifugation (**Figure 50.9**). If a sample of blood is spun in a centrifuge, all the cells move to the bottom of the tube, leaving the clear, straw-colored plasma on top. The *packed-cell volume*, or *hematocrit*, is the percentage of the blood volume made up by cells. Normal hematocrit is about 42 percent for women and 46 percent for men, but these values can vary considerably. They are usually higher, for example, in people who live and work at high altitudes, because the low oxygen concentrations there stimulate the production of more red blood cells.

Here we will consider two elements in blood: the *red blood cells* and the *platelets*, which are pinched-off fragments of cells. *White blood cells*, or *leukocytes*, are the cells of the immune system, which we discussed in Chapter 42.

Red blood cells transport respiratory gases

Most of the cells in the blood are **erythrocytes**, or red blood cells. Mature red blood cells are biconcave, flexible discs packed with hemoglobin. Their function is to transport respiratory gases. Their shape gives them a large surface area for gas exchange,

50.9 The Composition of Blood Blood consists of a complex aqueous solution (the plasma) and numerous cell types and cell fragments. The hematocrit (arrow) is a measure of the cellular portion as a percentage of total blood volume.

and their flexibility enables them to squeeze through narrow capillaries. Men have 4.5 to 6.0 million red blood cells per microliter of blood, and women have 3.5 to 5.0 million.

Red blood cells, as well as all the other cellular components of blood, are generated by stem cells in the bone marrow, particularly in the ribs, breastbone, pelvis, vertebrae, and the long bones of the limbs. Red blood cell production is controlled by a hormone, **erythropoietin**, which is released by cells in the kidneys in response to insufficient oxygen—**hypoxia**. Many tissues respond to hypoxia by expressing a transcription factor called *hypoxia-inducible factor 1 (HIF-1)*. When the kidneys become hypoxic and express HIF-1, one of the actions of the transcription factor is to activate the gene encoding erythropoietin. Increased circulating erythropoietin extends the lives of mature red blood cells and stimulates production of new red blood cells in the bone marrow.

Under normal conditions, your bone marrow produces about 2 million red blood cells every second. Developing, immature red blood cells divide many times while still in the bone marrow, and during this time they produce hemoglobin. When the hemoglobin content of a red blood cell approaches about 30 percent, the nucleus, endoplasmic reticulum, Golgi apparatus, and mitochondria of the cell begin to break down. This process is almost complete when the new red blood cell squeezes between the endothelial cells of blood vessels in the bone marrow and enters the circulation. Loss of nuclei from the red blood cells occurs in most mammalian species, but the red cells of some mammals and of all other vertebrates are nucleated.

Each red blood cell circulates for about 120 days. As it gets older, its membrane becomes less flexible and more fragile. Therefore, old red blood cells can rupture as they bend to fit through narrow capillaries. One place where they are really squeezed is in the **spleen**, an organ that sits near the stomach in the upper left side of the abdominal cavity. The spleen has many venous cavities, or sinuses, that serve as a reservoir for red blood cells, but to get into the sinuses, the red blood cells must squeeze between spleen cells. When old red blood cells are ruptured by this squeezing, their remnants are taken up and degraded by macrophages (a class of white blood cells that ingest debris and foreign materials).

Platelets are essential for blood clotting

Besides producing erythrocytes and leukocytes, the bone marrow stem cells described in Section 42.1 also produce cells called *megakaryocytes*. Megakaryocytes are large cells that remain in the bone marrow and release cell fragments called **platelets** into the circulation. A platelet is just a tiny fragment of a cell without cell organelles, but it is packed with enzymes and chemicals necessary for its function: sealing leaks in blood vessels and initiating **blood clotting** (Figure 50.10).

Damage to a blood vessel exposes collagen fibers. An encounter with collagen fibers activates a platelet. The platelet swells, becomes irregularly shaped and sticky, and releases chemicals that activate other platelets and initiate the clotting of blood. The sticky platelets also form a plug at the damaged site.

Blood clotting requires many steps and many clotting factors, most of which are circulating in the blood in an inactive form. The absence of any one of these proteins can impair clotting and cause excessive bleeding. Because the liver produces

50.10 Blood Clotting (A) Damage to a blood vessel initiates a cascade of events that produce a fibrin meshwork. (B) As the meshwork forms, red blood cells are enmeshed in the fibrin threads, forming a clot, as shown in this color-enhanced electron micrograph.

most of the clotting factors, liver diseases such as hepatitis and cirrhosis can result in excessive bleeding. People with hemophilia experience uncontrolled bleeding because of a genetic inability to produce one of the clotting factors.

Blood clotting factors participate in a cascade of chemical activations of other substances circulating in the blood. The cascade begins with blood vessel and other tissue damage that exposes the blood to proteins such as collagen that are normally separated from the blood by endothelial cells lining the blood vessels. This exposure activates platelets and begins the clotting factor cascade. The end result of this cascade is to convert an inactive circulating enzyme, **prothrombin**, to its active form, **thrombin**. Thrombin cleaves molecules of **fibrinogen**, a plasma protein, forming insoluble threads of **fibrin**. The fibrin threads form the meshwork that binds platelets, seals the vessel, and provides a scaffold for the formation of scar tissue (see Figure 50.10).

Blood circulates throughout the body in a system of blood vessels

As we mentioned in Section 50.1, blood circulates through the vertebrate body in a system of closed vessels. Blood leaves the heart in arteries and is distributed throughout the body's tissues in arterioles, which feed capillary beds. Exchanges of nutrients, wastes, respiratory gases, and hormones occur in the capillaries. Blood leaving capillary beds collects in venules, which empty into veins that conduct the blood back to the heart.

The walls of the large arteries have many extracellular collagen and elastin fibers, which enable them to withstand the high blood pressures generated by the heart (Figure 50.11A). These elastic tissues have another important function: they are stretched during systole, and thereby store some of the energy imparted to the blood by the heart. Elastic recoil during dias-

tole returns this energy to the blood by squeezing it and pushing it forward. As a result, even though pressure in the arteries pulsates with the beating of the heart, the flow of blood is smoother than it would be through a system of rigid pipes.

Smooth muscle cells in the walls of the arteries and arterioles constrict or dilate those vessels. When the diameter of the vessels changes, their resistance to blood flow also changes, and the amount of blood flowing through them changes as a result. Neural and hormonal mechanisms act on smooth muscle cells in the walls of the arteries and arterioles, controlling the flow of blood through these vessels. The arterioles are referred to as *resistance vessels* because their resistance can vary to control the blood flow to specific tissues.

Materials are exchanged in capillary beds by filtration, osmosis, and diffusion

Beds of capillaries lie between arterioles and venules (Figure 50.11B). Few cells are more than a few cell diameters away from a capillary. (Notable exceptions include developing oocytes and the cells of the lens and cornea.) The cells' needs are served by the exchange of materials between blood and interstitial fluid across the capillary walls. This exchange is facilitated by the capillaries' thin, permeable walls, as well as by the slow flow of blood through the capillaries.

It may seem strange that blood flows through the large arteries rapidly at high pressures, but when it reaches the small capillaries, the pressure and rate of flow decrease (Figure 50.11C). When you restrict the diameter of a garden hose by placing your thumb over the opening, the pressure in the hose increases, which in turn increases the velocity of the water spraying out of the hose. But keep in mind that the arteries branch into many arterioles, which give rise to a huge number of capillaries. Even

50.11 Anatomy of Blood Vessels (A) The different anatomical characteristics of arteries and veins match their functions. (B) Blood from the arterial system feeds into capillary beds, where exchanges with the interstitial fluid occur. The venous system returns the blood to the heart. (C) The area encompassed by each vessel type is graphed along with the pressure and velocity of the blood within them.

yourBioPortal.com

GO TO Web Activity 50.3 • Structure of a Blood Vessel

Blood pressure is high at the arterial end of a capillary bed and steadily drops as blood moves towards the venous end (**Figure 50.13**). The osmotic pressure is due to the large protein molecules that cannot leave the capillaries, and it is relatively constant along the capillaries. As long as the blood pressure is above the osmotic pressure, fluid leaves the capillaries. At the venule end of most capillaries, blood pressure falls below the osmotic pressure, so fluid returns to the capillaries. The actual numbers for a normal capillary bed in a resting person suggest that there would be a *slight* net loss of fluid to the intercellular spaces. This loss, about 4 liters per day, percolates between cells as the interstitial fluid before it returns to the venous blood via the lymphatic system, which we will discuss later in this chapter.

Several observations supported Starling's model. In people with severe liver disease or protein starvation, a fall in blood protein concentration leads to an accumulation of fluid in the extracellular spaces, which results in tissue swelling, or *edema*. Edema is also characteris-

though each capillary has a diameter so small that red blood cells must pass through in single file, there are so many capillaries that their total cross-sectional area is much greater than that of any other class of vessels. As a result, all the capillaries together have a much greater capacity for blood than do the arterioles. Returning to our garden hose analogy, if we connected the hose to an increasing number of lawn sprinklers, eventually the pressure and flow in each sprinkler would be low.

Capillary walls consist of a single layer of thin endothelial cells (**Figure 50.12**). In most tissues of the body other than the brain, capillaries have tiny holes, or *fenestrations* (*fenestra*, “windows”). Capillaries are permeable to water, some ions, and some small molecules but not to large molecules such as proteins. At the arterial (high pressure) end, blood pressure squeezes water and some small solutes out of the capillaries and into the surrounding intercellular spaces. Why don't water and small-molecular-weight solutes collect in the intercellular spaces? How is the blood volume maintained if fluid is continuously leaking out of the capillaries?

An answer to this question was put forth more than 100 years ago by the physiologist E. H. Starling. Starling suggested that water movement across capillary walls is a result of two opposing forces, which are now known as **Starling's forces**:

- Blood pressure squeezes water and small solutes out of the capillaries.
- Osmotic pressure pulls water back into the capillaries.

50.12 A Narrow Lane Capillaries have a very small diameter, and blood flows through them slowly.

50.13 Starling's Forces Starling's model explains how blood volume is maintained in the capillary beds. (A) When blood pressure is greater than osmotic pressure, fluid leaves the capillaries; when blood pressure falls below osmotic pressure, fluid returns to the capillaries. (B) The balance of these two forces changes over the capillary bed as blood pressure falls.

tic of the inflammation response accompanying tissue damage or allergic responses (see Figure 42.3). *Histamine*, a mediator of inflammation released by certain white blood cells, increases capillary permeability and relaxes the smooth muscles of the arterioles, raising blood pressure in the capillaries and leading to fluid leakage into tissues.

A few situations are not explained by Starling's hypothesis. During strenuous exercise, the blood pressure in the arterioles serving the muscles rises substantially but does not result in edema. In birds, the blood pressure in arterioles is much higher than in mammals, and the osmotic pressure is lower. If edema is not a chronic problem in exercising muscles and in birds, what is missing from Starling's model?

Recent research suggests that bicarbonate ions (HCO_3^-) in the blood plasma contribute significantly to the osmotic attraction that draws water back into the capillaries. The CO_2 produced by cellular metabolism diffuses into the endothelial cells lining the capillaries, where it is converted into HCO_3^- and released into the plasma. When the subject is at rest, the increasing HCO_3^- concentration can cause the osmotic pressure of the blood at the venous end to be 30 mm Hg higher than at the arterial end, and during strenuous exercise this difference can be

much higher. Thus it appears that CO_2 and HCO_3^- are major factors that pull water back into the capillaries.

Lipid-soluble substances and many small solute molecules can easily pass through capillary walls from an area of higher concentration to one of lower concentration. The capillaries in different tissues, however, are differentially selective as to the sizes of molecules that can pass through them. You can imagine that this is an important issue in the design and delivery of drugs. All capillaries are permeable to O_2 , CO_2 , glucose, lactate, and small ions such as Na^+ and Cl^- . However, the capillaries of the brain do not have fenestrations, and therefore not much else can pass through them other than lipid-soluble substances, such as alcohol and anesthetics. This high selectivity of brain capillaries is known as the *blood-brain barrier*.

Much less selective capillaries are found in the digestive tract, where nutrients are absorbed, and in the kidneys, where wastes are filtered. Even in the brain there are specific regions where the capillaries are more permeable, enabling the brain to detect non-lipid soluble hormones.

Blood flows back to the heart through veins

The pressure of the blood flowing from capillaries to venules is extremely low and is insufficient to propel blood back to the heart. The walls of veins are more expandable than the walls of arteries, and blood tends to accumulate in veins. As much as 60 percent of your total blood volume may be in your veins when you are resting. Because of their high capacity to stretch and store blood, veins are called *capacitance vessels*.

Blood flow through veins that are above the level of the heart is assisted by gravity. Below the level of the heart, however, venous return is against gravity. The most important force propelling blood from these regions is the squeezing of the veins by the contractions of surrounding skeletal muscles. As muscles contract, the vessels are compressed and blood is squeezed through them. Blood flow may be temporarily obstructed during a prolonged muscle contraction, but when muscles relax, blood is free to move again. One-way valves in the veins of the extremities prevent backflow of blood. Thus, whenever a vein is squeezed, blood is propelled forward toward the heart (**Figure 50.14**).

In a resting person, gravity causes blood accumulation in the veins of the lower body and exerts backpressure on the capillary beds. This backpressure shifts the balance between blood pressure and osmotic pressure, causing increased loss of fluid to the intercellular spaces. That is why your feet swell during a long airline flight.

Because of the one-way valves in the veins of the legs, the contractions of leg muscles act as auxiliary vascular pumps when an animal walks or runs and facilitate the return of blood to the heart from the veins of the lower body. As a greater volume of blood is returned to the heart, the heart contracts more forcefully and its pumping action is enhanced. The heartbeat gets stronger because of a property of cardiac muscle cells described by the **Frank-Starling law**: if the cardiac muscle cells are stretched, as they are when the volume of returning blood increases, they contract more forcefully.

50.14 One-Way Flow Veins have valves that prevent blood from flowing backward, and contractions of skeletal muscle help move blood toward the heart.

The actions of breathing also help return venous blood to the heart. The muscles involved in inhalation create negative pressure that pulls air into the lungs (see Figure 49.11), and this negative pressure also pulls blood toward the chest, increasing venous return to the right atrium. In addition, some of the largest veins closest to the heart contain smooth muscle that contracts at the onset of exercise. Contraction of veins can rapidly increase venous return and stimulate the heart in accord with the Frank–Starling law, increasing cardiac output.

Lymphatic vessels return interstitial fluid to the blood

The interstitial fluid contains water and small molecules, but no red blood cells, and less protein than found in plasma. A separate system of vessels—the **lymphatic system**—returns interstitial fluid to the blood. Each capillary bed contains at least one blind-ended lymph capillary.

Once it enters the lymphatic vessels, the interstitial fluid is called **lymph**. Fine lymphatic capillaries merge into progressively larger vessels and ultimately into two lymphatic vessels—the **thoracic ducts**—that empty into large veins at the base of the neck (see Figure 42.1). The left thoracic duct carries most of the lymph from the lower part of the body and is much larger than the right thoracic duct. Lymph, like blood, is propelled to-

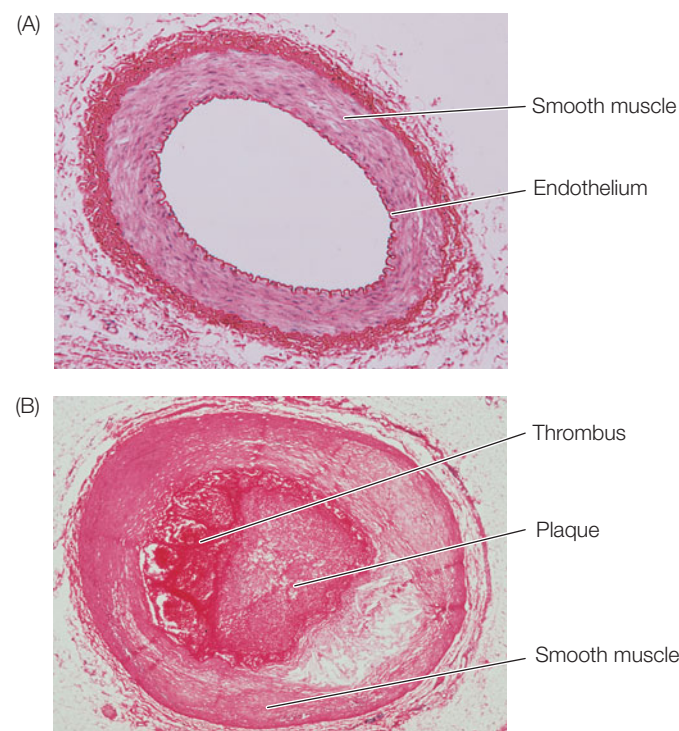

ward the heart by skeletal muscle contractions and breathing movements, and lymphatic vessels, like veins, have one-way valves that keep the lymph flowing toward the thoracic duct.

Mammals and birds have **lymph nodes** along the major lymphatic vessels. Lymph nodes are a major site of lymphocyte production and of the phagocytic action that removes microorganisms and other foreign materials from the circulation (see Section 42.1).

Vascular disease is a killer

As mentioned at the start of this chapter, cardiovascular disease is responsible for about one-fourth of all deaths each year in the United States, and the same is true for Europe. The immediate cause of most of these deaths is not a defect in heart muscle, as it is in athletes. Instead, the cause is mostly heart attack or stroke, which are usually the end result of a disease called **atherosclerosis** (“hardening of the arteries”) that begins many years before symptoms are detected.

Healthy arteries have a smooth internal lining of endothelial cells (**Figure 50.15A**) that can be damaged by chronic high blood pressure, smoking, a high-fat diet, or microorganisms. Deposits called **plaque** begin to form at sites of endothelial damage. First, the damaged endothelial cells attract certain white blood cells to the site. These cells are then joined by smooth muscle cells migrating from the deeper layers of the arterial wall. Lipids, especially cholesterol, are deposited in these cells, so that the developing plaque becomes fatty. Fibrous connective tissue made by the invading smooth muscle cells in the plaque, along with

50.15 Atherosclerotic Plaque (A) A healthy, clear artery. (B) An atherosclerotic artery, clogged with plaque and a thrombus.

deposits of calcium, make the artery wall less elastic—hence, “hardening of the arteries.” The growing plaque deposit narrows the artery and causes turbulence in the blood flow. Blood platelets stick to the plaque (see Figure 50.10) and initiate formation of an intravascular blood clot, a **thrombus**, which can block the artery (Figure 50.15B).

The blood supply to the heart muscle flows through the **coronary arteries** which are highly susceptible to atherosclerosis. As these arteries narrow, blood flow to the heart muscle decreases, causing the symptoms of chest pain and shortness of breath during mild exertion. A person with atherosclerosis is at high risk of forming a thrombus in a coronary artery. This condition, called **coronary thrombosis**, can totally block the vessel, causing a *heart attack*, or **myocardial infarction**.

A piece of a thrombus that breaks loose, called an **embolus**, is likely to travel to and become lodged in a vessel of smaller diameter, blocking its flow (an **embolism**). Arteries already narrowed by plaque formation are likely places for an embolism. An embolism in an artery in the brain causes the cells fed by that artery to die. This event is a **stroke**. The specific damage resulting from a stroke, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery.

Probably the most important determinants of whether you will get atherosclerosis are your genetic predisposition and your age. Environmental risk factors play a large role, however. If you do have a genetic predisposition to atherosclerosis, it is even more important to minimize environmental risk factors. These include high-fat and high-cholesterol diets, smoking, and a sedentary lifestyle. Certain untreated medical conditions such as *hypertension* (high blood pressure), obesity, and diabetes are also risk factors for atherosclerosis. Changes in diet and behavior and treatment of predisposing medical conditions can prevent and reverse early atherosclerosis and help fend off this silent killer.

50.4 RECAP

Blood is a fluid tissue with cellular components that play roles in transport of respiratory gases, immune system function, and blood clotting. Blood is distributed throughout the body in a system of vessels. Exchanges between the blood and interstitial fluids occur in the smallest of those vessels, the capillaries.

- How are the structural differences between the various classes of vessels related to their functions? See pp. 1058–1061 and Figure 50.11
- Why are arterioles called resistance vessels and veins called capacitance vessels? See pp. 1058 and 1060
- What factors control the movement of fluids between the vascular and extravascular spaces? See pp. 1059–1060 and Figure 50.13
- What propels blood from the lower part of the body back to the heart? See pp. 1060–1061 and Figure 50.14

Every tissue in the body requires an adequate flow of oxygen-saturated blood that carries essential nutrients and is relatively free of waste products. Blood flow depends on the maintenance of an appropriate blood pressure, and the distribution of blood flow throughout the body depends on control of the resistance in the blood vessels supplying different tissues.

50.5 How Is the Circulatory System Controlled and Regulated?

When we investigate how a physiological process is regulated, we start by identifying the critical components of that process, how they can be controlled, and the information used to govern that control. Because blood flow depends on pressure, we can identify the pressure in the aorta as a critical variable of the circulatory system. The pressure in the aorta oscillates between systole and diastole, so we define our variable as the *mean arterial pressure* (MAP). MAP is determined by the cardiac output (CO) and the resistance to flow in the blood vessels, or *total peripheral resistance* (TPR):

$$\text{MAP} = \text{CO} \times \text{TPR}$$

Since CO is a function of the heart rate (HR) and stroke volume (SV), however, the critical relationships we have to understand can be expressed as:

$$\text{MAP} = \text{HR} \times \text{SV} \times \text{TPR}$$

HR, SV, and TPR are controlled by neural and hormonal mechanisms at both the local and systemic levels. At the local level, each tissue controls its own blood flow through **autoregulatory mechanisms** that cause the arterioles supplying that tissue to constrict or dilate.

The collective autoregulatory actions in the capillary beds in all tissues of the body determine TPR and therefore MAP. If many arterioles suddenly dilate, TPR goes down and MAP falls. If many arterioles constrict, TPR goes up and MAP goes up. Changes in MAP provide information about changing needs of the body. As blood flows through capillary beds, its composition changes; its CO₂ content goes up and its O₂ content goes down. Thus, blood composition also provides information the body uses to regulate the circulatory system.

The nervous and endocrine systems respond to changes in MAP and blood composition by changing breathing rate, heart rate, stroke volume, and peripheral resistance to match the metabolic needs of the body. We will now see how these mechanisms work.

Autoregulation matches local blood flow to local need

The amount of blood that flows through a capillary bed is controlled by the smooth muscle of the arteries and arterioles feeding that bed. Figure 50.16 illustrates the flow of blood in a typical capillary bed. Blood flows into the bed from an arteriole. Smooth muscle “cuffs,” or **precapillary sphincters**, on the arteriole can shut off the supply of blood to the capillary bed. When the precapillary sphincters are relaxed and the arteriole is open, the arterial blood pressure pushes blood into the capillaries.

50.16 Local Control of Blood Flow Low O_2 concentrations or high levels of metabolic by-products cause the smooth muscle of the arteries and arterioles to relax, thus increasing the supply of blood to the capillary bed.

Autoregulation depends on the sensitivity of the smooth muscle to its local chemical environment. Low O_2 concentrations and high CO_2 concentrations cause the smooth muscle to relax, thus increasing the supply of blood, which brings in more O_2 and carries away CO_2 —a response known as **hyperemia**, which means “excess blood.” Increases in other by-products of metabolism, such as lactic acid, hydrogen ions, potassium, and adenosine (all of which increase in exercising muscle), promote hyperemia through the same mechanism. Hence, activities that increase the metabolism of a tissue also induce hyperemia in that tissue.

Arterial pressure is regulated by hormonal and neural mechanisms

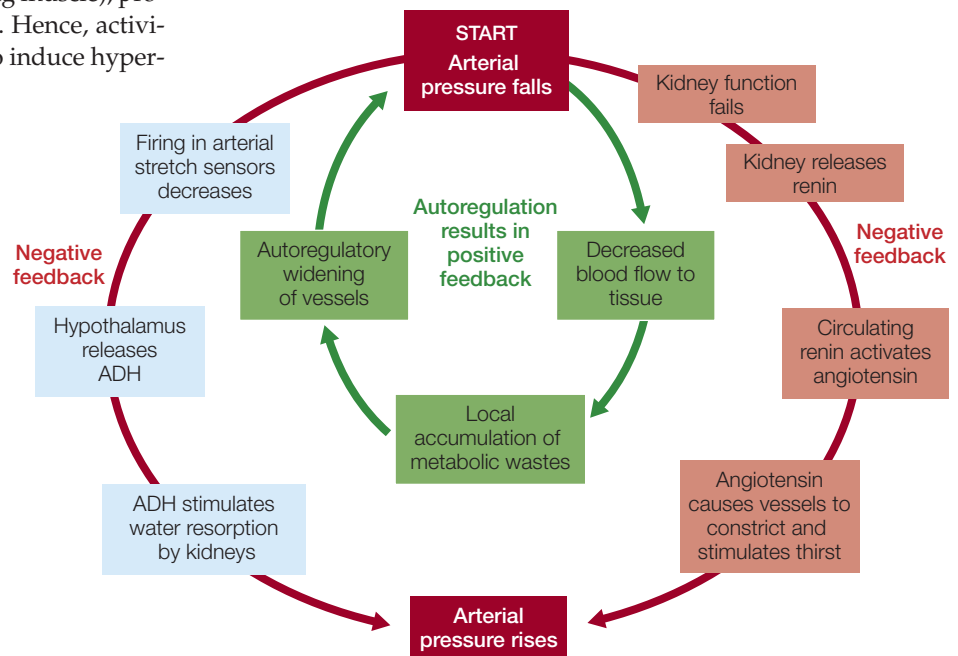

Control and regulation of the circulatory system begins with the local autoregulatory mechanisms that alter the resistance of arteries and arterioles feeding capillary beds. The demands of the capillary beds influence MAP and blood composition. Both of these provide information for the control of endocrine and neural responses that act to return blood pressure and composition to normal. Thus circulatory functions are matched to the regional and overall needs of the body.

Arteries and arterioles are innervated by the autonomic nervous system, particularly the sympathetic division. The sympathetic postganglionic neurotransmitter norepinephrine binds to receptors in smooth muscle in blood vessels in the gut and other tissues not essential for “fight or flight” and causes these

vessels to constrict, resulting in reduced blood flow through them and an elevation in MAP. In skeletal muscle, however, specialized sympathetic neurons release acetylcholine, causing the smooth muscle of these arterioles to relax and the vessels to dilate, increasing blood to flow to the muscle. As we discussed earlier in this chapter, increased sympathetic activity increases heart rate, and by increasing the strength of the cardiac muscle contraction, it also increases stroke volume.

Hormones also play a role in regulating arterial pressure. *Epinephrine* has actions similar to those of norepinephrine and is released from the adrenal medulla during massive sympathetic activation stimulated by a fall in arterial pressure or by activation of the fight-or-flight response to a dangerous threat. Another hormone, *angiotensin*, is produced when blood pressure to the kidneys falls (**Figure 50.17**). These hormones influence arterioles located for the most part in peripheral tissues (extremities) or in tissues whose functions need not be maintained continuously (such as the gut). By reducing blood flow in those arterioles, these hormones increase central blood pressure and blood flow to essential organs such as the heart, brain, and kidneys.

The autonomic nervous system activity that controls heart rate and constriction of blood vessels originates in a cardiovascular control center in the medulla. Many inputs converge on this central integrative network and influence the commands it issues via parasympathetic and sympathetic nerves (**Figure 50.18**). Of special importance is incoming information about changes in blood pressure and composition from both **baroreceptors** (stretch receptors) and **chemoreceptors** in the walls of the large arteries leading to the brain—the aorta and the carotid arteries.

50.17 Control of Blood Pressure through Local and Systemic Mechanisms A drop in arterial pressure reduces blood flow to tissues, resulting in local accumulation of metabolic wastes. This change in the extracellular environment stimulates autoregulatory opening of the arteries. A fall in central blood pressure is prevented by negative feedback mechanisms that constrict arteries in less essential tissues and stimulate maintenance of blood volume and blood pressure.

Increased activity in baroreceptors of the large arteries signals rising blood pressure and inhibits sympathetic nervous system signaling to arteries and arterioles while increasing parasympathetic signaling to the heart's pacemaker (see Figure 50.5). As a result, the heart slows and arterioles in peripheral tissues dilate, reducing blood pressure. If pressure in the large arteries falls, the activity of the baroreceptors decreases, stimulating sympathetic output to the arteries and arterioles while reducing parasympathetic output to the heart's pacemaker. As a result, the heart beats faster and the arterioles in peripheral tissues constrict, increasing blood pressure.

50.18 Regulating Cardiac Output The autonomic nervous system controls heart rate in response to information about blood pressure and blood composition originating in baroreceptors and chemosensors shown at the bottom of the figure. Information from these sensors goes to the cardiovascular control center in the medulla, where it is integrated with other information. The medullary center generates responses in the sympathetic and parasympathetic nervous systems that control cardiac output.

Another hormone that helps stabilize blood pressure is antidiuretic hormone (ADH, also called vasopressin), which is secreted by the posterior pituitary in response to a fall in the activity of the baroreceptors, signaling a fall in arterial pressure. ADH causes the kidneys to resorb more water and thereby maintain blood volume and increase blood pressure. Increased activity of the baroreceptors inhibits the release of ADH, and as a result the kidneys excrete more water, reducing blood volume and contributing to a fall in arterial pressure (see Figure 50.17).

Other information that causes the cardiovascular control center to increase heart rate and blood pressure comes from chemoreceptors in the medulla, aorta, and the carotid arteries. As we discussed in Section 49.5, the medullary chemosensors are activated by increases in arterial CO_2 levels, and the carotid and aortic bodies are activated by falls in arterial O_2 levels. Chemosensors send signals to the cardiovascular regulatory center as well as to the respiratory regulatory center.

50.5 RECAP

The delivery of blood to tissues is controlled locally by autoregulatory mechanisms that dilate or constrict arterioles. These local actions are translated into alterations in central blood pressure and composition that are detected by neural and hormonal mechanisms, which then mediate corrective cardiovascular adjustments.

- How do autoregulatory changes in blood flow to capillary beds result in adjustments to MAP? **See pp. 1062–1063 and Figure 50.16**
- What are the roles of hormones in regulating blood pressure? **See p. 1063 and Figure 50.17**
- Describe the role of baroreceptors and chemoreceptors in regulating blood pressure. **See pp. 1063–1064 and Figure 50.18**

CHAPTER SUMMARY

50.1 Why Do Animals Need a Circulatory System?

- The metabolic needs of the cells of many small animals are met by direct exchange of materials with the external medium. The metabolic needs of the cells of larger animals are met by a **circulatory system** that transports nutrients, respiratory gases, and metabolic wastes throughout the body.

- In **open circulatory systems**, extracellular fluid leaves vessels and percolates through tissues. In **closed circulatory systems**, the blood is contained in a system of vessels. Closed circulatory systems have several advantages, including the ability to selectively direct blood, hormones, and nutrients to specific tissues. **Review Figure 50.1**

50.2 How Have Vertebrate Circulatory Systems Evolved?

SEE WEB ACTIVITY 50.1

- The circulatory system of vertebrates consists of a heart and a closed system of vessels containing blood that is separate from the interstitial fluid. **Arteries** and **arterioles** carry blood from the heart; **capillaries** are the site of exchange between blood and interstitial fluid; **venules** and **veins** carry blood back to the heart.
- The vertebrate heart evolved from two chambers in fishes to three in amphibians and some reptiles and four in crocodilians, birds, and mammals. This evolutionary progression has led to an increasing separation of blood that flows to the gas exchange organs and blood that flows to the rest of the body.
- The simplest (two-chambered heart) has an **atrium** that receives blood from the body and a **ventricle** that pumps blood out of the heart. An **aorta** distributes blood to arteries.
- In birds and mammals, blood circulates through two completely separate circuits: the **pulmonary**, which transports blood between the heart and lungs, and the **systemic**, which transports oxygen-rich blood between the heart and tissues.

50.3 How Does the Mammalian Heart Function?

- The human heart has four chambers. Valves in the heart prevent the backflow of blood. **Review Figure 50.2, WEB ACTIVITY 50.2**
- The **cardiac cycle** has two phases: **systole**, in which the ventricles contract, and **diastole**, in which the ventricles relax. The sequential heart sounds (“lub-dup”) are made by the closing of the heart valves. **Review Figure 50.3, ANIMATED TUTORIAL 50.1**
- Blood pressure can be measured using a sphygmomanometer and a stethoscope. **Review Figure 50.4**
- The autonomic nervous system controls heart rate: sympathetic activity increases heart rate, and parasympathetic activity decreases it. Norepinephrine increases and acetylcholine decreases the rate of depolarization of the plasma membranes of **pacemaker cells**, affecting heart rate. **Review Figure 50.5**
- The **sinoatrial node** controls the cardiac cycle by initiating a wave of depolarization in the atria, which is conducted to the ventricles through a system consisting of the **atrioventricular node**, **bundle of His**, and **Purkinje fibers**. **Review Figure 50.6**
- Sustained contraction of ventricular muscle cells is due to long-duration action potentials that are generated by voltage-gated Na^+ and Ca^{2+} channels. **Review Figure 50.7**
- An **electrocardiogram (ECG)** records electrical events associated with the contraction and relaxation of the cardiac muscles. **Review Figure 50.8**

50.4 What Are the Properties of Blood and Blood Vessels?

- Blood can be divided into a **plasma** portion (water, salts, and proteins) and a cellular portion (**erythrocytes** or red blood cells, platelets, and white blood cells). All of the cellular components are produced from stem cells in the bone marrow. **Review Figure 50.9**
- Erythrocytes transport oxygen. Their production in the bone marrow is stimulated by **erythropoietin**, which is produced in response to **hypoxia** (low oxygen levels) in the tissues.
- **Platelets**, along with circulating proteins, are involved in **blood clotting**, which results in a meshwork of **fibrin** threads that help seal vessels. **Review Figure 50.10**
- Abundant smooth muscle cells allow vessels to change their diameter, altering their resistance and thus blood flow. Arteries and arterioles have many elastic fibers that enable them to withstand high pressures. **Review Figure 50.11, WEB ACTIVITY 50.3**
- Capillary beds are the site of exchange of materials between blood and tissue fluid.
- **Starling’s forces** suggest that blood volume is maintained in the capillary beds by an exchange of fluids driven by both blood pressure and osmotic pressure. **Review Figure 50.13**
- An accumulation of fluid in the extracellular spaces leads to **edema**. Bicarbonate ions in the blood plasma contribute to the osmotic forces that draw water back into capillaries.
- The ability of a specific molecule to cross a capillary wall depends on the architecture of the capillary, the type of substance, and the concentration gradient between the blood and the tissue fluid.
- Veins have a high capacity for storing blood. Aided by gravity, by contractions of skeletal muscle, and by the actions of breathing, they return blood to the heart. **Review Figure 50.14**
- The **Frank–Starling law** describes forces that increase cardiac output, such as stretch of the cardiac muscles cells caused by increased venous return.
- The **lymphatic system** returns the interstitial fluid to the blood.

50.5 How Is the Circulatory System Controlled and Regulated?

- Blood flow through capillary beds is controlled by local **autoregulatory mechanisms**, hormones, and the autonomic nervous system. **Review Figure 50.16**
- Blood pressure is controlled in part by the hormones ADH and angiotensin, which stimulate contraction of blood vessels. **Review Figure 50.17**
- Heart rate is controlled by the autonomic nervous system, which responds to information about blood pressure and blood composition that is integrated by regulatory centers in the medulla. **Review Figure 50.18**

SELF-QUIZ

1. An open circulatory system is characterized by
 - a. the absence of a heart.
 - b. the absence of blood vessels.
 - c. blood with a composition different from that of tissue fluid.
 - d. the absence of capillaries.
 - e. a higher-pressure circuit through gills than to other organs.
2. Which statement about vertebrate circulatory systems is *not* true?
 - a. In fish, oxygenated blood from the gills returns to the heart through the left atrium.
 - b. In mammals, deoxygenated blood leaves the heart through the pulmonary artery.

- c. In amphibians, deoxygenated blood enters the heart through the right atrium.
 - d. In reptiles, the blood in the pulmonary artery has a lower oxygen content than the blood in the aorta.
 - e. In birds, the pressure in the aorta is higher than the pressure in the pulmonary artery.
- Which statement about the human heart is *true*?
 - The walls of the right ventricle are thicker than the walls of the left ventricle.
 - Blood flowing through atrioventricular valves is always deoxygenated blood.
 - The second heart sound is due to the closing of the aortic valve.
 - Blood returns to the heart from the lungs in the vena cava.
 - During systole, the aortic valve is open and the pulmonary valve is closed.
 - The pacemaker action potentials in the heart
 - are due to opposing actions of norepinephrine and acetylcholine.
 - are generated by the bundle of His.
 - depend on the gap junctions between the cells that make up the atria and those that make up the ventricles.
 - are due to spontaneous depolarization of the plasma membranes of modified cardiac muscle cells.
 - result from hyperpolarization of cells in the sinoatrial node.
 - Blood velocity through capillaries is slow because
 - much blood volume is lost from the capillaries.
 - the pressure in venules is high.
 - the total cross-sectional area of capillaries is larger than that of arterioles.
 - the osmotic pressure in capillaries is very high.
 - erythrocytes must pass through in single file.
 - How are lymphatic vessels like veins?
 - Both have nodes where they join together into larger common vessels.
 - Both carry blood under low pressure.
 - Both are capacitance vessels.
 - Both have valves.
 - Both carry fluids rich in plasma proteins.
 - The production of erythrocytes
 - ceases if the hematocrit falls below normal.
 - is stimulated by erythropoietin.
 - is about equal to the production of white blood cells.
 - is inhibited by prothrombin.
 - occurs in bone marrow before birth and in lymph nodes after birth.
 - Which of the following does *not* increase blood flow through a capillary bed?
 - High concentration of CO₂
 - High concentration of lactate and hydrogen ions
 - Histamine
 - ADH
 - Increase in arterial pressure
 - Blood clotting
 - is impaired in patients with hemophilia because they do not produce platelets.
 - is initiated when platelets release fibrinogen.
 - involves a cascade of factors produced in the liver.
 - is initiated by leukocytes forming a meshwork.
 - requires production of angiotensin.
 - Autoregulation of blood flow to a tissue is due to
 - sympathetic innervation.
 - the release of ADH by the hypothalamus.
 - increased activity of baroreceptors.
 - chemoreceptors in the aorta and the carotid arteries.
 - the effect of the local chemical environment on arterioles.

FOR DISCUSSION

- At the beginning of a race, cardiac output increases immediately before there is any change in blood O₂ or CO₂ concentrations. Explain two factors that contribute to this effect. Include the Frank–Starling law in your answer.
- Explain how the hearts of crocodilians have the advantages of mammalian hearts during exercise but the efficiency of reptilian hearts during rest.
- A sudden and massive loss of blood results in a decrease in blood pressure. Describe several mechanisms that help return blood pressure to normal.
- You can describe the cycle of events in a ventricle of the heart by a graph that plots the pressure in the ventricle on the *y* axis and the volume of blood in the ventricle on the *x* axis. What would such a graph look like? Where would the heart sounds be on this graph? How would the graph differ for the left and the right ventricles?
- If the major arteries become clogged with plaque and become less elastic because of atherosclerosis, the left ventricle must work harder and harder to pump an adequate supply of blood to the body. As a result, the left ventricle can become weakened and begin to fail, even though the right ventricle is healthy. A heart attack primarily affecting the left ventricle can have the same effect. This condition is known as congestive heart failure, and it commonly leads to fatal pulmonary edema. Explain how left ventricular failure can result in pulmonary edema, and why is it said that this condition creates a vicious circle that makes itself worse rapidly.

ADDITIONAL INVESTIGATION

- There are strains of rats that are spontaneously hypertensive—they naturally have high blood pressure. Can you formulate a hypothesis about the basis for such inherited hypertension and explain experiments you would do to test your hypothesis?
- If you were in training to compete in the Tour de France, a grueling 3-week-long bicycle race, a trainer might tell you to “train high, compete low.” What do you think is the physiological basis for such advice, and how would you test whether or not that reasoning was correct?

51

Nutrition, Digestion, and Absorption

An obesity epidemic

For thousands of years, the Pima of southwestern North America were hunters and gatherers who supplemented their diet with subsistence agriculture. Their environment was arid, so they developed sophisticated irrigation systems; even so, they frequently encountered drought and subsequent starvation. Today most individuals of the ethnic Pima population in North America are clinically obese. In fact, as a population, they are one of the heaviest in the world.

With obesity come related health problems such as diabetes, high blood pressure, and heart disease. The incidence of diabetes among the Pima rose from an extremely high level of 45 percent of adults in 1965 to a staggering 80 percent in 1999. Moreover, diabetes is occurring in younger individuals than ever before. What has caused such a radical health change in an entire population? At least two interacting factors are involved: genetics and lifestyle.

Geneticists hypothesize that recurring episodes of starvation produce strong selective pressure for “thrifty genes”—particular alleles of the genes involved in digestion, absorption, and energy storage that result in greater-than-average efficiency in converting food into energy and into energy reserves, such as fat. Thrifty genes would give individuals a strong selective advantage when food is scarce. An example of a “thrifty” phenotype is seen among the Pima. They have a very low resting metabolic rate and convert food into fat readily. As we will see later in this chapter, the hormone insulin facilitates the conversion of dietary sugar into fat tissue. For many Pima, consuming a standard amount of glucose causes their insulin levels to rise three times higher than it does in Americans of European ancestry.

The other factor in the Pima obesity epidemic is an abrupt change in their traditional lifestyle. When food is plentiful and has high caloric content, thrifty genes con-

Efficiency Genes The Pima are an example of a human population that repeatedly experienced periods of severe food deprivation. These historic occurrences may have imposed selection for genes that improve the efficiency of managing the energy obtained from food. With modern diets and lifestyles, these “efficiency genes” can contribute to obesity.

The Great American Lunch High-fat fast foods have become prevalent in much of the developed world. A steady diet of such foods will mean weight gain for most people, and is a major reason for obesity in the United States.

tribute to obesity by maximizing fat storage. Today the Pima eat a modern Western diet that includes high-fat, high-calorie fast foods. In general, they also engage in less physical activity than their ancestors did.

A comparative study supports the hypotheses that have been put forward to explain the obesity epidemic in the Pima. Another population of Pima live in the Sierra Madre of northern Mexico. Genetically, they are the same as the Arizona population. However, they live a traditional lifestyle and eat traditional foods. Whereas the Arizona Pima engage in an average of only 2 hours of physical work per week, the Mexico Pima average 23 hours per week. Obesity and diabetes are not prevalent among the Mexico Pima.

A high-calorie diet and sedentary lifestyle affect not just the Pima but contribute to the overall increase in obesity throughout the U.S. population. Researchers are studying the Pima to learn more about the genetics of obesity and related pathologies.

IN THIS CHAPTER we will review the nutrients organisms require for energy, for molecular building blocks, and for specific biochemical functions. We will examine diverse adaptations for acquiring, ingesting, and digesting food and absorbing nutrients. Finally, we will learn how the body regulates its traffic in metabolic fuels and return to the question of control of body mass.

CHAPTER OUTLINE

- 51.1** What Do Animals Require from Food?
- 51.2** How Do Animals Ingest and Digest Food?
- 51.3** How Does the Vertebrate Gastrointestinal System Function?
- 51.4** How Is the Flow of Nutrients Controlled and Regulated?

51.1 What Do Animals Require from Food?

Animals are **heterotrophs**—they derive their nutrition from eating other organisms. In contrast, **autotrophs** (most plants, some bacteria, some archaea, and some protists) can use solar energy or inorganic chemical energy to synthesize all of their components. Directly and indirectly, heterotrophs take advantage of—indeed, depend on—the organic synthesis carried out by autotrophs, and have evolved an enormous diversity of adaptations to exploit this resource (**Figure 51.1**). In this section we will discover how animals use food, be it plants or other animals, to obtain energy and building blocks of complex molecules. We will also consider the need for special mineral nutrients and organic molecules we call vitamins and the diseases that result when they are lacking in the diet.

Energy needs and expenditures can be measured

Energy is the capacity to do work, and it comes in different forms—electrical energy, heat energy, chemical energy, nuclear energy. As discussed in Chapter 8, a *calorie* (note the small *c*) is a unit of heat energy; specifically, it is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. Since this is a tiny amount of energy, physiologists commonly use the **kilocalorie (kcal)** as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie as a standard unit of energy, but they traditionally refer to it as the **Calorie (Cal)** which is always capitalized to distinguish it from the single calorie.

Just about any food container you pick up in the U.S. carries a label, “Nutrition Facts,” that includes the item “Calories.” How do Calories (or kcal) relate to the discussion in Chapter 9 about how energy in the chemical bonds of food molecules is transferred to the high-energy phosphate bonds of adenosine triphosphate (ATP) and is then used to do cellular work? And why do we use heat energy as a measure of nutrition?

The reason is found in the laws of thermodynamics, which tell us that energy cannot be created or destroyed, but can be converted from one form to another (see Section 8.1). However, every energy conversion is inefficient and a large portion of the original energy always ends up as heat. Whether we are using the energy in glucose to make ATP or are using that ATP to power muscle contraction or ion transport, most of the available chemical energy is lost as heat. The bottom line is that if an animal is not growing, not doing work on its environment, and not changing its body temperature, the heat it loses to the environment is a measure of its total energy expenditure—its *metabolic rate*.

(A)

51.1 Heterotrophs Get Energy from Autotrophs (A) Herbivores get their energy directly from autotrophs. The large herbivores of the African grasslands must consume huge amounts of plant matter to fulfill their nutritional needs. (B) A carnivore's energy is indirectly obtained from autotrophs, since the energy stored in a prey animal was originally obtained from autotrophs.

(B)

The metabolic rate of an animal is a measure of its overall energy needs that must be met by the ingestion, digestion, and assimilation of food (see Section 40.3). The basal metabolic rate of a human is 1,300–1,500 Cal/day for an adult female and 1,600–1,800 Cal/day for an adult male. Physical activity adds to this basal energy requirement. For a person doing sedentary work, about 30 percent of the Calories expended are used for skeletal muscle activity; for a person doing heavy physical labor, more than 95 percent of total caloric expenditure is due to skeletal muscle activity.

The components of food that provide energy are fats, carbohydrates, and proteins. Fats yield 9.5 Cal/gram, carbohydrates 4.2 Cal/gram, and proteins about 4.1 Cal/gram. **Figure 51.2** shows some equivalencies of food, energy, and energy consumption.

Even though the units calorie, kilocalorie, and Calorie remain in popular use, most scientists now use the International System of Units. In this system, the basic unit of energy is the joule: 1 joule = 0.239 calories, and the measure of energy utilization is 1 joule/second = 1 watt. You are familiar with light bulb ratings, so think about that when you convert kcal/day into watts. The metabolic rate of the average man is 1,700 kcal/day or 82 watts (note that a watt includes the time dimension, so it is a rate of energy utilization).

Thus it is possible to quantify the caloric value of any food an animal eats. It is also possible to quantify the caloric expenditure of any activity or behavior an animal performs. By comparing calories consumed with calories expended, we can construct *energy budgets* that allow ecologists and evolutionary biologists to apply a *cost–benefit analysis* to feeding behavior, as we explain in Section 53.4.

51.2 Food Energy and How We Use It The energy contained in several common food items is shown at the left. The graphs indicate about how long it would take a person with a basal metabolic rate of about 1,800 Cal/day to utilize the equivalent amount of energy while resting, walking, or jogging.

Sources of energy can be stored in the body

Although the cells of the body use energy continuously, most animals do not eat continuously. Therefore, animals must store fuel molecules that can be released as needed between meals. Carbohydrates are stored in liver and muscle cells as glycogen, but the total glycogen store represents only about a day's basal energy requirements (1,500–2,000 Cal). Fat is the most important form of stored energy in the bodies of animals. Not only does fat have more energy per gram than glycogen, but it can be stored with little associated water, making it more compact. Migrating birds store energy as fat to fuel their long flights; if they had to store the same amount of energy as glycogen, they would be too heavy to fly! Proteins are not used as energy storage compounds, although body protein can be metabolized as an energy source of last resort.

If an animal takes in too little food to meet its energy requirements, it is **undernourished** and must start metabolizing some of the molecules of its own body. This “self-consumption” begins with the energy storage compounds glycogen and fat. There is some protein loss due to normal protein turnover not being fully replaced because of a lack of amino acids for new protein synthesis. Once fat reserves are seriously depleted, the body increases its metabolism of proteins for energy (**Figure 51.3A**). The first proteins to be sacrificed are those of the blood plasma. The loss of plasma proteins decreases the osmotic concentration of the plasma, resulting in increased loss of fluid from the blood to the interstitial spaces (*edema*; see Section 50.4). Accumulation of fluid in the extremities and abdomen is the classic sign of *kwashiorkor*, a disease caused by chronic protein deficiency (**Figure 51.3B**). Continued protein loss damages the body's organs, leading eventually to death.

When an animal consistently takes in more food than it needs to meet its energy requirements, it is **overnourished**, and the excess nutrients are stored as increased body mass. First, glycogen reserves build up; then additional dietary carbohydrates, fats, and proteins are converted to body fat. In some species, such as hibernators, seasonal overnutrition is an important adaptation for surviving periods when food is not available. In humans, however, overnutrition can be a serious health hazard, increasing the risk of high blood pressure, heart attack, diabetes, and other disorders.

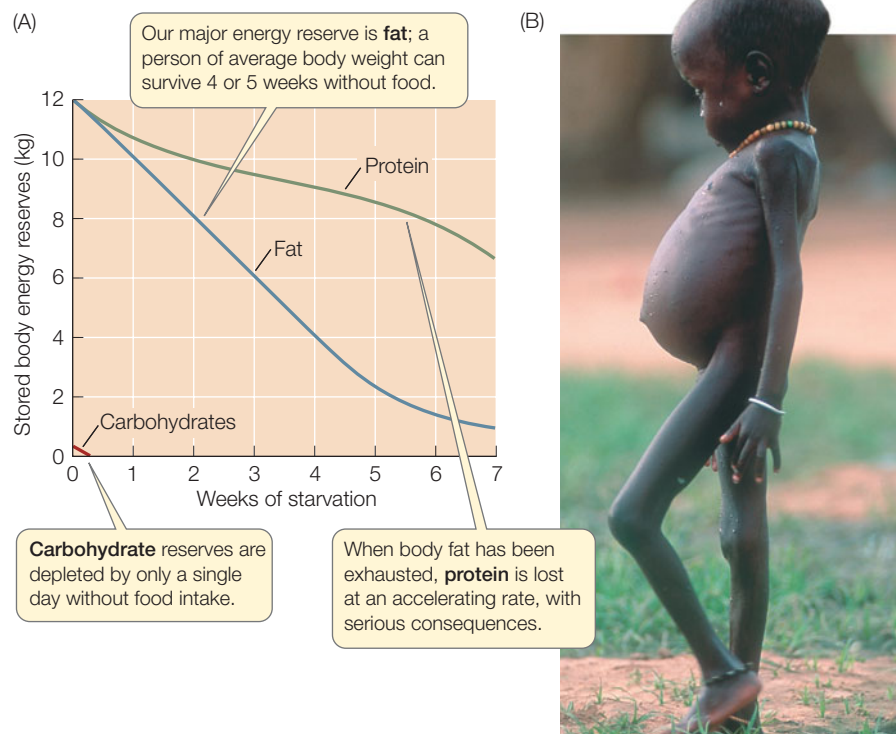

Food provides carbon skeletons for biosynthesis

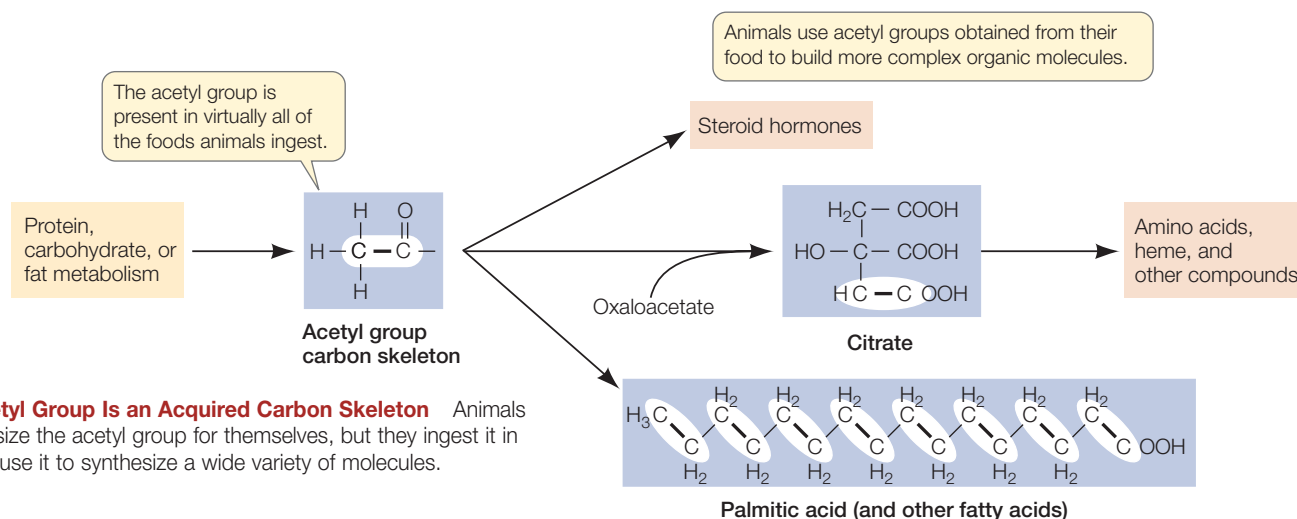

Every animal requires certain basic organic molecules that it cannot synthesize for itself but needs as building blocks for its own complex organic molecules. The acetyl group ($\text{CH}_3\text{CO}-$) is one such required building block supplying the **carbon skeleton** of larger organic molecules (**Figure 51.4**). Animals cannot make acetyl groups from carbon, oxygen, and hydrogen molecules; they must obtain acetyl groups from food. Acetyl groups can be derived from the metabolism of almost any food, but they originate in plants. Acetyl groups are never in short supply for an adequately nourished animal. However, some groups supplying carbon skeletons can be deficient in an animal's diet even if caloric intake is adequate.

Amino acids, the building blocks of proteins, are a good example of carbon skeletons that can be in short supply. Animals can synthesize some of their own amino acids by utilizing carbon skeletons from acetyl or other groups and transferring to them amino groups ($-\text{NH}_2$) derived from other amino acids. Most animals cannot synthesize all the amino acids they need. Each species must obtain certain **essential amino acids** from food. Essential amino acids vary by species. In general, herbivores have fewer essential amino acids than carnivores. If an animal does not take in enough of even one of its essential amino acids, its protein synthesis is impaired and its capacity to maintain enzymatic and transport functions is challenged.

Most researchers agree that adult humans must obtain eight essential amino acids from their food: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. All eight are available in milk, eggs, meat, and soybean products, but most plant foods do not contain adequate quantities

51.3 The Course of Starvation (A) In a person subjected to undernutrition, the body's energy reserves are eventually depleted. (B) The swollen abdomen, face, hands, and feet of this Somali girl are due to edema. Along with her spindly limbs, these are symptoms of *kwashiorkor*, a syndrome resulting from the body breaking down blood proteins and muscle tissue to fuel metabolism.

51.4 The Acetyl Group Is an Acquired Carbon Skeleton Animals cannot synthesize the acetyl group for themselves, but they ingest it in their food and use it to synthesize a wide variety of molecules.

of all eight, so a strict vegetarian diet carries a risk of protein malnutrition. A *complementary* diet of plant foods, however, supplies all eight essential amino acids (**Figure 51.5**). In general, grains (such as rice, wheat, and corn) are complemented by legumes (such as beans and peas). Long before the chemical basis for this complementarity was understood, societies with little access to meat developed complementary diets. Many Central and South American peoples traditionally eat beans with corn, and the native peoples of North America complemented their beans with squash.

Human infants are thought to require four additional amino acids in their diets: histidine, tyrosine, cysteine, and arginine. Also, some amino acids are *conditionally essential* for certain populations that cannot synthesize them in adequate amounts. For example, individuals with the genetic disease phenylketonuria lack the enzyme for converting phenylalanine to tyrosine (see Section 15.3) and thus must obtain tyrosine from their diets. They must keep their dietary intake of phenylalanine low to prevent its accumulation to toxic levels.

Why are dietary proteins completely digested to their constituent amino acids before being used by the body? Wouldn't it be more energy-efficient to reuse some dietary proteins directly? There are several reasons why ingested proteins are not used "as is":

- Macromolecules such as proteins are not readily absorbed by the cells of the gut, but their constituent monomers (such as amino acids) are readily absorbed.
- Protein structure and function are highly species-specific. A protein that functions optimally in one species might not function well in another.
- Foreign proteins entering the body directly from the gut would be recognized as invaders and would be attacked by the immune system.

Humans can synthesize almost all the lipids required by the body using acetyl groups obtained from food (see Figure 51.4), but we must have a dietary source of certain **essential fatty acids**—notably, linoleic acid—that we cannot synthesize. Linoleic acid is an unsaturated fatty acid needed by mammals to synthesize other unsaturated fatty acids, such as arachidonic acid, which is a component of several signaling molecules, including prostaglandins. Essential fatty acids are also necessary components of membrane phospholipids. A deficiency of linoleic acid can lead to problems such as infertility and impaired lactation, but since it is commonly present in vegetable oils, a deficiency is unlikely in an adequately nourished individual.

Animals need mineral elements for a variety of functions

Table 51.1 lists the principal mineral elements that animals require. Elements required in large amounts are called **macronutrients**; those required in only tiny amounts (generally less than 100 mg/day) are called **micronutrients**. Some micronutrients are required in such minute amounts that deficiencies are never observed, but they are nevertheless essential elements.

Calcium is an example of a macronutrient. It is the fifth most abundant element in the body; a 70-kg person contains about 1.2 kg of calcium. Calcium phosphate is the principal structural material in bones and teeth. Muscle contraction, neural function, and many other intracellular functions in animals require calcium ions (Ca^{2+}). The turnover of calcium in the extracellular fluid is high, as bones are constantly being remodeled and calcium is constantly entering and leaving cells. Calcium is lost from the body

51.5 A Strategy for Vegetarians By combining cereal grains with legumes, an adult vegetarian can obtain all eight essential amino acids.

TABLE 51.1

Mineral Elements Required by Animals

ELEMENT	SOURCE IN HUMAN DIET	MAJOR FUNCTIONS
MACRONUTRIENTS		
Calcium (Ca)	Dairy foods, eggs, green leafy vegetables, whole grains, legumes, nuts, meat	Found in bones and teeth; blood clotting; nerve and muscle action; enzyme activation
Chlorine (Cl)	Table salt (NaCl), meat, eggs, vegetables, dairy foods	Water balance; digestion (as HCl); principal negative ion in extracellular fluid
Magnesium (Mg)	Green vegetables, meat, whole grains, nuts, milk, legumes	Required by many enzymes; found in bones and teeth
Phosphorus (P)	Dairy, eggs, meat, whole grains, legumes, nuts	Found in nucleic acids, ATP, and phospholipids; bone formation; buffers; metabolism of sugars
Potassium (K)	Meat, whole grains, fruits, vegetables	Nerve and muscle action; protein synthesis; principal positive ion in cells
Sodium (Na)	Table salt, dairy foods, meat, eggs	Nerve and muscle action; water balance; principal positive ion in extracellular fluid
Sulfur (S)	Meat, eggs, dairy foods, nuts, legumes	Found in proteins and coenzymes; detoxification of harmful substances
MICRONUTRIENTS		
Chromium (Cr)	Meat, dairy, whole grains, legumes, yeast	Glucose metabolism
Cobalt (Co)	Meat, tap water	Found in vitamin B ₁₂ ; formation of red blood cells
Copper (Cu)	Liver, meat, fish, shellfish, legumes, whole grains, nuts	Found in active site of many redox enzymes and electron carriers; production of hemoglobin; bone formation
Fluorine (F)	Most water supplies	Found in teeth; helps prevent decay
Iodine (I)	Fish, shellfish, iodized salt	Found in thyroid hormones
Iron (Fe)	Liver, meat, green vegetables, eggs, whole grains, legumes, nuts	Found in active sites of many redox enzymes and electron carriers, hemoglobin, and myoglobin
Manganese (Mn)	Organ meats, whole grains, legumes, nuts, tea, coffee	Activates many enzymes
Molybdenum (Mo)	Organ meats, dairy, whole grains, green vegetables, legumes	Found in some enzymes
Selenium (Se)	Meat, seafood, whole grains, eggs, milk, garlic	Fat metabolism
Zinc (Zn)	Liver, fish, shellfish, and many other foods	Found in some enzymes and some transcription factors; insulin physiology

in urine, sweat, and feces, so it must be replaced regularly. Humans require 800–1,000 mg of calcium per day in their diet.

Iron is an example of a micronutrient. It is found throughout the body because it is the oxygen-binding atom in hemoglobin and myoglobin and is a component of enzymes in the electron transport chain. Nevertheless, the total amount of iron in a 70-kg person is only about 4 grams, and since iron is recycled efficiently in the body and is not lost in the urine, we require only about 15 mg per day in our food. Despite the small amount required, insufficient iron is the most common mineral nutrient deficiency in the world today, leading to *anemia*. Anemic individuals are weak and tired all the time.

Animals must obtain vitamins from food

Like essential amino acids and fatty acids, **vitamins** are carbon compounds that an animal requires for growth and metabolism

but cannot synthesize for itself. They are required in very small amounts compared with the essential amino acids and fatty acids, which are incorporated into large body structures. Most vitamins function as coenzymes or parts of coenzymes.

The list of vitamins varies from species to species. Most mammals, for example, can make their own ascorbic acid. Primates (including humans) cannot, so for primates, ascorbic acid is a vitamin—*vitamin C*. If we do not get vitamin C in our food, we develop a disease known as scurvy, characterized by bleeding gums, loss of teeth, subcutaneous hemorrhages, and slow wound healing. The disease was a frequently fatal problem for sailors on long voyages until a Scottish physician, James Lind, discovered that scurvy could be prevented if the sailors ate fresh greens and citrus fruit. The British Admiralty made limes standard provisions for its ships (and British sailors have been called “limeys” ever since). When the active ingredient in limes was isolated, it was named *ascorbic* (“without scurvy”) *acid*.

Humans require 13 vitamins (Table 51.2). They are divided into two groups: water-soluble and fat-soluble. When water-soluble vitamins are ingested in excess of bodily needs, they are

TABLE 51.2
Vitamins in the Human Diet

VITAMIN	SOURCE	FUNCTION	DEFICIENCY SYMPTOMS
WATER-SOLUBLE			
B ₁ (thiamin)	Liver, legumes, whole grains	Coenzyme in cellular respiration	Beriberi, loss of appetite, fatigue
B ₂ (riboflavin)	Dairy, meat, eggs, green leafy vegetables	Coenzyme in FAD	Lesions in corners of mouth, eye irritation, skin disorders
Niacin	Meat, fowl, liver, yeast	Coenzyme in NAD and NADP	Pellagra, skin disorders, diarrhea, mental disorders
B ₆ (pyridoxine)	Liver, whole grains, dairy foods	Coenzyme in amino acid metabolism	Anemia, slow growth, skin problems, convulsions
Pantothenic acid	Liver, eggs, yeast	Found in acetyl CoA	Adrenal problems, reproductive problems
Biotin	Liver, yeast, bacteria in gut	Found in coenzymes	Skin problems, loss of hair
B ₁₂ (cobalamin)	Liver, meat, dairy foods, eggs	Formation of nucleic acids, proteins, and red blood cells	Pernicious anemia
Folic acid	Vegetables, eggs, liver, whole grains	Coenzyme in formation of heme and nucleotides	Anemia
C (ascorbic acid)	Citrus fruits, tomatoes, potatoes	Formation of connective tissues; antioxidant	Scurvy, slow healing, poor bone growth
FAT-SOLUBLE			
A (retinol)	Fruits, vegetables, liver, dairy	Found in visual pigments	Night blindness
D (cholecalciferol)	Fortified milk, fish oils, sunshine	Absorption of calcium and phosphate	Rickets
E (tocopherol)	Meat, dairy foods, whole grains	Muscle maintenance, antioxidant	Anemia
K (menadione)	Intestinal bacteria, liver	Blood clotting	Blood-clotting problems

simply eliminated in the urine. (This is the fate of much of the excess vitamin C that people take.) Fat-soluble vitamins, however, can accumulate in body fat and may build up to toxic levels in the liver if taken in excess.

The fat-soluble vitamin D (cholecalciferol), which is essential for absorbing and metabolizing calcium, is a special case because the body can synthesize it. (As noted in Section 41.3, vitamin D is by definition a hormone.) Certain lipids present in the human body can be converted into vitamin D by the action of ultraviolet light on the skin. Thus vitamin D must be obtained in the diet by individuals with inadequate exposure to the sun.

The need for vitamin D may have been an important factor in the evolution of skin color. Human races that are adapted to equatorial and low latitudes have dark skin pigmentation as a protection against the damaging effects of ultraviolet radiation. These peoples generally expose extensive areas of skin to the sun on a regular basis, so their skin synthesizes adequate amounts of vitamin D. Most races that adapted to life in the higher latitudes lost this dark skin pigmentation, probably because lighter skin facilitates vitamin D production in the relatively small areas of skin exposed to sunlight during the short days of winter. The Inuit peoples of the Arctic seem to represent an exception to the correlation between latitude and skin pigmentation, but these dark-skinned people obtain ample vitamin D from the large amounts of animal fat (especially whale blubber) and fish oils in their diet.

Nutrient deficiencies result in diseases

The lack of any essential nutrient in the diet produces a state of deficiency called **malnutrition**, and chronic malnutrition leads to a characteristic **deficiency disease**. We have already discussed kwashiorkor (protein deficiency) and scurvy (vitamin C deficiency). A shortage of any of the vitamins results in specific deficiency symptoms (see Table 51.2). Another deficiency disease, *beriberi*, was directly involved in the discovery of vitamins.

Beriberi means “extreme weakness.” It became prevalent in Asia in the nineteenth century after it became standard practice to mill rice to a high, white polish and discard the hulls present in brown rice. A critical observation was that birds—chickens and pigeons—developed beriberi-like symptoms when fed only polished rice. In 1912, Casimir Funk, a Polish scientist working in England, cured pigeons of beriberi by feeding them discarded rice hulls.

At the time of Funk’s discovery, all diseases were thought to be either caused by microorganisms or inherited. Funk suggested the radical idea that beriberi and some other diseases are dietary in origin and result from deficiencies in specific substances. Funk coined the term “vitamines” because he mistakenly thought that all these substances vital for life were compounds with amino groups (vital amines). In 1926, thiamin (vitamin B₁)—the substance lost in the rice milling process—was the first vitamin to be isolated in pure form.

Deficiency diseases can also result from an inability to absorb or process an essential nutrient even if it is present in the diet. Vitamin B₁₂ (cobalamin), for example, is present in all foods

of animal origin. Since plants neither use nor produce vitamin B₁₂, a strictly vegetarian diet (not supplemented with dairy products or vitamin pills) can lead to a B₁₂ deficiency disease called pernicious anemia, characterized by a failure of red blood cells to mature. The most common cause of pernicious anemia, however, is not a lack of vitamin B₁₂ in the diet but an inability to absorb it. Normally, cells in the stomach lining secrete a peptide called *intrinsic factor*, which binds to vitamin B₁₂ and makes it possible for it to be absorbed in the small intestine. Conditions that damage the stomach lining, such as alcoholism or gastritis, can thus lead to pernicious anemia.

Inadequate mineral nutrition can also lead to deficiency diseases. Examples are hypothyroidism and goiter resulting from iodine deficiency (see Section 41.3), and anemia resulting from iron deficiency. Iodine deficiency is almost unheard of today in the developed world because of the addition of iodide to salt. However, it is still a major health problem in large segments of the human population. Probably the single least expensive effective action to improve global health would be to provide iodized salt for everyone.

51.1 RECAP

As heterotrophs, animals must obtain the energy and molecular building blocks for biosynthesis from their food. Energy can come from the metabolism of carbohydrates, fats, and proteins. Molecular building blocks include carbon skeletons, vitamins, and minerals.

- Explain the different roles of food energy from proteins, carbohydrates, and fats in the mammalian body. **See p. 1070 and Figure 51.3**
- Give an example of an essential carbon skeleton, a micronutrient, and a macronutrient. **See pp. 1070–1073, Figure 51.4 and Table 51.1**
- Why should fat-soluble vitamins not be taken in excess? **See p. 1073**

We have surveyed the essential elements of nutrition in animals. Next we will look at various methods and adaptations by which animals obtain the food they need, and mechanisms by which the food is processed in the body to extract nutrients.

51.2 How Do Animals Ingest and Digest Food?

Heterotrophic organisms can be classified by how they acquire their nutrition. **Saprobies** (also called *saprotrophs* or *decomposers*) are organisms—mostly protists and fungi—that absorb nutrients from dead organic matter. **Detritivores**, such as earthworms and crabs, actively feed on dead organic material. Animals that feed on living organisms are **predators**: **herbivores** prey on plants, **carnivores** prey on animals, and **omnivores** prey on both. **Filter feeders**, such as clams and blue whales, prey on small organisms by filtering them from the aquatic environment. **Fluid**

feeders include mosquitoes, aphids, leeches, and hummingbirds. The anatomical adaptations that enable a species to exploit a particular source of nutrition are usually obvious, but physiological and biochemical adaptations are also important.

The food of herbivores is often low in energy and hard to digest

Most vegetation is coarse and difficult to break down, but herbivores process large amounts of it because its energy content is low. Therefore, herbivores spend a great deal of time feeding. Many have striking adaptations for feeding, such as the trunk (a flexible, gripping nose) of the elephant or the huge bill of the fruit-eating toucan, which can be half as long as its body. Many types of grinding, rasping, cutting, and shredding mouthparts have evolved in invertebrates for ingesting plant material, and the teeth of herbivorous vertebrates have been shaped by selection to tear, crush, and grind coarse plant matter.

The digestive processes of herbivores can also be quite specialized. An example is the koala, which almost exclusively eats leaves of eucalyptus trees. These leaves are very fibrous, low in usable energy and protein, and high in toxic chemicals. Koalas actually smell like eucalyptol, a common ingredient in cough drops. The koala has strong jaws for grinding the leaves, a very long gut for fermenting them, enzymes in its liver for detoxifying chemicals in the leaves, and a low metabolic rate to compensate for low energy intake.

Carnivores must detect, capture, and kill prey

The predatory behaviors of many carnivores are legendary—the hunting skills of hawks, wolves, and tigers, for example. Carnivores have evolved stealth, speed, power, large jaws, sharp teeth, and strong gripping appendages. They also have evolved remarkable means of detecting prey. Bats use echolocation, pit vipers sense infrared radiation from the warm bodies of their prey, and certain fishes detect electric fields created in the water by their prey.

Adaptations for killing and ingesting prey are diverse and can be highly specialized. These adaptations are especially important when the prey can inflict damage on the predator. There are many fascinating examples of adaptations for capturing and immobilizing prey, such as the immobilizing venom in the bite of many snakes, the long sticky tongues of chameleons, and the webs of spiders. The long tentacles of certain jellyfish contain some of the most deadly toxins known and can kill humans. Specialized cells called *nematocysts* inject toxin into the victim (see Figure 31.9). Some jellyfish harbor enough nematocysts cells to kill 50 people. Some predators digest their prey externally. For example, a spider injects its insect prey with digestive enzymes and then sucks out the liquefied contents, leaving behind the empty exoskeletons frequently seen in old spider webs.

Vertebrate species have distinctive teeth

Teeth are adapted for the acquisition and initial processing of specific types of foods. Because they are among the hardest struc-

51.6 Mammalian Teeth (A) A mammalian tooth has three layers: enamel, dentine, and a pulp cavity. (B) The teeth of different mammalian species are specialized for different diets. This illustration depicts the teeth of the lower jaw, viewed from above.

—yourBioPortal.com—

GO TO Web Activity 51.3 • Mammalian Teeth

tures of the body, an animal's teeth remain in the environment long after it dies. Paleontologists use teeth to identify animals that lived in the distant past and to deduce their feeding behavior.

All mammalian teeth have the same general, three-layered structure (**Figure 51.6A**). An extremely hard material called **enamel**, composed principally of calcium phosphate, covers the crown of the tooth. Both the crown and root contain a layer of bony material called **dentine**, inside of which is a **pulp cavity** containing blood vessels, nerves, and the cells that produce the dentine.

There is a great deal of homology in the dentition of mammals, but the shapes and organization of mammalian teeth are adaptations to different diets (**Figure 51.6B**). In general, *incisors* are used for cutting, chopping, and gnawing; *canines* are used for stabbing, gripping, and ripping; and *molars* and *premolars* (the cheek teeth) are used for shearing, crushing, and grinding. The highly varied diet of humans is reflected in our multipurpose set of teeth, as is common among omnivores.

Digestion usually begins in a body cavity

Animals take food into a body cavity that is continuous with the outside environment. They secrete digestive enzymes into that cavity, and the enzymes break down the food into nutrient molecules that can be absorbed by the cells lining the cavity.

The simplest digestive systems are **gastrovascular cavities**, which connect to the outside world through a single opening. Cnidarians, such as the jellyfish mentioned above, capture prey using stinging nematocysts and use their tentacles to cram the prey into their gastrovascular cavities. Enzymes in the gastrovascular

cavity partly digest the prey. Cells lining the cavity take in small food particles by endocytosis. The vesicles created by endocytosis then fuse with lysosomes containing digestive enzymes, and intracellular digestion completes the breakdown of the food. Nutrients are released to the cytoplasm as the vesicles break down.

Tubular guts have an opening at each end

The guts of most animals are tubular: a **mouth** takes in food; molecules are digested and absorbed throughout the length of the gut; and solid digestive wastes are eliminated through an **anus**. Different regions in the tubular gut are specialized for particular functions (**Figure 51.7**). These functions must be coordinated so they occur in the proper sequence and at rates that maximize the efficiency of digestion and absorption of nutrients.

At the anterior end of the gut is the mouth cavity where food can be fragmented, for example by teeth (in many vertebrates), by **radula** (in snails), or by **mandibles** (in many arthropods). In most birds, food is ground by small stones in an early, muscular, portion of the gut called the **gizzard**. Some animals, such as snakes, simply ingest whole prey with little or no fragmentation. **Stomachs** and **crops** are storage chambers that enable animals to ingest relatively large amounts of food when it is available, then digest it gradually. In these storage chambers, food may be further fragmented and mixed, and in most vertebrates it is an important site of digestion. Food delivered into the next section of the gut, the **intestine**, is in small particles, well mixed, and usually partially digested.

Most digestion occurs in the intestine, and nutrients, water, and ions are absorbed across its walls. Glands secrete digestive enzymes into the intestine, and other enzymes are produced by cells lining the intestine. The final segment of the intestine recovers water and ions and stores undigested wastes, or **feces**, so they can be released to the environment at an appropriate

51.7 Compartments for Digestion and Absorption Most invertebrates and all vertebrates have a tubular gut that begins with a mouth, which takes in food, and ends in an anus, which eliminates wastes. Between these two structures are specialized regions for digestion and nutrient absorption; the structures in these regions are adapted to different diets and vary from species to species.

time or place. A muscular **rectum** near the anus assists in expelling feces.

Endosymbiotic bacteria colonize the intestines. These bacteria obtain their nutrition from the food passing through the host's gut while contributing to the host's digestive processes. Members of the leech genus *Hirudo*, for example, produce no enzymes that can digest the proteins in the blood they suck from vertebrates; instead, they depend on bacteria to perform this service. The resulting amino acids are subsequently used by both the leech and the bacteria.

The microorganisms in the human gut are called the “forgotten organ” because they provide important services in diges-

tion, elimination of harmful microorganisms, and even the production of vitamins (vitamin K and biotin). This forgotten organ is huge. It is estimated that the human body consists of 10^{13} cells, but our guts contain probably 10 times that number of unicellular organisms representing at least 500 different species. (And thus most of the DNA in our bodies is from alien species—an interesting thought.)

In many animals, the parts of the gut that absorb nutrients have greater surface areas than would be expected of a simple tube (**Figure 51.8A,B**). In vertebrates, the wall of the intestine is richly folded, with the individual folds bearing legions of tiny fingerlike projections called **villi** (**Figure 51.8C**). The cells that line the surfaces of the villi, in turn, have microscopic projections called **microvilli**. The microvilli give the intestine an enormous internal surface area for absorbing nutrients.

Digestive enzymes break down complex food molecules

Protein, carbohydrate, and fat macromolecules are broken down into their simplest monomeric units by hydrolytic enzymes produced at different locations in the digestive tract. Many are secreted into the lumen of the gut, and others remain associated with the membranes of the microvilli. All of these enzymes cleave the chemical bonds of macromolecules through *hydrolysis*, a reaction that adds a water molecule (see Figure 3.4B). Digestive enzymes are classified according to the substances they hydrolyze: *proteases* break the bonds between adjacent amino acids in proteins; *carbohydrases* hydrolyze carbohydrates; *peptidases*, peptides; *lipases*, fats; and *nucleases*, nucleic acids.

How can an organism produce enzymes that hydrolyze biological macromolecules without digesting itself? Many digestive enzymes are produced in an inactive form known as a **zymogen**, so that they cannot act on the cells that produce them. When secreted into the gut, a zymogen is generally activated by another enzyme. The cells lining the gut are not digested because they are protected by a covering of mucus.

51.2 RECAP

Heterotrophs have diverse adaptations for acquiring food. Once captured and/or ingested, food is digested extracellularly by secreted enzymes to release nutrients, which are absorbed into the animal's body, usually via a tubular gut.

- Why do herbivores typically spend a great deal of their time feeding? **See p. 1074**
- What is the primary purpose of the intestinal microvilli? **See p. 1076 and Figure 51.8**
- What is a zymogen, and why is it important? **See p. 1076**

Once ingested by an animal, food may be fragmented and moved into the gut for digestion by hydrolytic enzymes. The processes of digestion release the nutrients needed by the animal. Let's focus next on how those processes occur in vertebrates.

(A) Earthworm

(B) Shark

(C) Human

51.8 Intestinal Surface Area and Nutrient Absorption Maximizing the surface area of the gut increases an animal's ability to absorb nutrients.

51.3 How Does the Vertebrate Gastrointestinal System Function?

Digestion in vertebrates occurs in the gastrointestinal system, which includes a tubular gut running from mouth to anus and several accessory structures that produce secretions that play important roles in digestion (**Figure 51.9**). In this section we will consider three important processes of this system: the movement of food through it, the sequential steps of digestion, and the absorption of nutrients. Our focus will be the human system.

The vertebrate gut consists of concentric tissue layers

The tissues of the vertebrate gut are arranged in concentric layers that have a similar organization throughout its

51.9 The Human Digestive System Different compartments in the long tubular gut specialize in digesting food, absorbing nutrients, and storing and expelling wastes. Accessory organs contribute secretions containing enzymes and other molecules.

yourBioPortal.com

GO TO Web Activity 51.4 • The Human Digestive System

51.10 Tissue Layers of the Vertebrate Gut The organization of tissue layers is the same in all compartments of the gut, but specialized adaptations of specific tissues characterize different regions.

length (**Figure 51.10**). Starting in the cavity, or **lumen**, the first layer is the **mucosa**, which consists of delicate epithelial cells underlain by connective tissue. Some cells of this *mucosal epithelium* have secretory and absorptive functions. Some secrete mucus, which lubricates and protects the walls of the gut; others secrete digestive enzymes or hormones. Mucosal epithelial cells in the stomach secrete hydrochloric acid (HCl) and, as we noted in Section 51.1, some secrete intrinsic factor to aid the absorption of vitamin B₁₂. In some regions of the gut, nutrients are absorbed by mucosal epithelial cells. The apical plasma membranes of these absorptive cells have microvilli that increase the surface area over which absorption can take place (see **Figure 51.8C**).

At the base of the mucosa are some smooth muscle cells that can move the mucosa to improve contact with gut contents, and just under the mucosa is the submucosal tissue layer. Here we find the blood and lymph vessels that carry absorbed nutrients to the rest of the body. The **submucosa** also contains a network of nerves; the neurons in this network have sensory functions (responsible for stomach aches) and control various secretory functions of the gut.

External to the submucosa are two layers of smooth muscle responsible for the large movements of the gut. Innermost is the *circular muscle layer*, with its cells oriented around the gut. Outermost is the *longitudinal muscle layer*, with its cells oriented along the length of the gut (see **Figure 51.10**). The circular muscles constrict the gut, and the longitudinal muscles shorten it. Between the two layers of smooth muscle is another nerve network which controls and coordinates the movements of the gut. The coordinated activity of the two smooth muscle layers mixes the content of the gut and moves it continuously toward the rectum. Interestingly, the stomach has a third layer of smooth muscle that is closest to the lumen. The orientation of its fibers is oblique to

the longitudinal and circular layers. This third layer is important in generating the churning motions of the stomach.

The nerve nets in the submucosa and between the smooth muscle layers are called the **enteric nervous system**, and they are unusual. Whereas most neurons of the peripheral nervous system either receive synapses from neurons in the central nervous system (CNS) or contribute synapses to neurons in the CNS, most of the neurons in the enteric nervous system form synapses only with other neurons in their network. Thus, they are responsible for communication within the gut. The CNS can influence the activity in enteric nervous system and receive information from it, but truly, the gut has a “mind” of its own.

A tissue membrane called the **peritoneum** surrounds the gut, as it does all of the organs of the abdominal cavity as well as lining the wall of the cavity. The peritoneum includes connective and epithelial tissues, which secrete a fluid that lubricates the organs so they can easily slide against each other in the body cavity.

Mechanical activity moves food through the gut and aids digestion

In humans and most other mammals, food is chewed in the mouth and mixed with saliva. Periodically the *tongue* pushes a *bolus* (mass) of the chewed food toward the throat. By making contact with the *soft palate* at the back of the mouth cavity, the food bolus initiates *swallowing*, which is a complex series of reflexes. Swallowing propels the food through the pharynx (where the mouth cavity and nasal passages join) and into the **esophagus** (food tube). To prevent food from entering the trachea (windpipe), the *larynx* (voice box) closes, and a flap of tissue called the *epiglottis* covers the entrance to the larynx (**Figure 51.11A**).

Once a bolus of food enters the esophagus, it is moved toward the stomach both by the force of gravity and by waves of muscle contraction called **peristalsis** (**Figure 51.11B**). The muscle of the upper region of the esophagus is striated (i.e., skeletal muscle) and is controlled by the central nervous system; the muscles of the rest of the esophagus are smooth muscle controlled by the autonomic and enteric nervous systems.

The smooth muscles of the gut contract in response to being stretched. When a bolus of food reaches the smooth-muscle region of the esophagus and stretches it, the muscle responds by contracting, thus pushing the food toward the stomach. Why doesn't the contraction of the esophageal smooth muscle push the food back toward the mouth? The nerve net between the two smooth muscle layers coordinates the muscles so that contraction is always preceded by an *anticipatory wave of relaxation*. When a region of the gut smooth muscle contracts, the circular smooth muscle just beyond it relaxes while the longitudinal smooth muscle contracts, pushing the food into that area. The resulting stretch causes that circular smooth muscle to contract while the next region relaxes. In this way peristalsis moves food down the gut from the mouth to the anus.

The backward movement of food from the stomach into the esophagus is prevented by the *lower esophageal sphincter*, a thick ring of circular smooth muscle at the junction of the esopha-

(A) Swallowing

(B) Peristalsis

51.11 Swallowing and Peristalsis (A) Food pushed to the back of the mouth triggers the swallowing reflex. (B) Once a food bolus enters the esophagus, peristalsis propels it from mouth to anus by coordinated actions of the circular and longitudinal muscle layers of the gut.

gus and stomach. This sphincter is normally constricted, but waves of peristalsis cause it to relax enough to let food pass from the esophagus into the stomach. Sphincter muscles are found elsewhere in the digestive tract as well. The *pyloric sphincter* governs the passage of stomach contents into the intestine. Two other important sphincters also control movement of gut contents: the *ileocaecal sphincter* between the small and large intestine, and the internal *anal sphincter* which has to relax to allow defecation.

Chemical digestion begins in the mouth and the stomach

The main role of the stomach is to store food so that digestion can occur more slowly than ingestion. However, the enzyme **amylase** is secreted by the salivary glands and mixed with food as it is chewed. Amylase hydrolyzes the bonds between the glucose monomers that make up starch molecules. The action of amylase is what makes a chewed piece of bread or cracker taste slightly sweet if you hold it in your mouth long enough.

The stomach also has secretory functions. Deep infoldings in the walls of the stomach called **gastric pits** are lined with three types of secretory cells (**Figure 51.12A**). One type secretes a proteolytic enzyme, **pepsin**, that begins the digestion of protein. Another type secretes hydrochloric acid (HCl), which kills most ingested microorganisms. This nasty mix of substances could damage the stomach walls, but a third cell type secretes mucus that provides a protective coating for the walls of the gastric pits and stomach. This mucus keeps the pH at the surface of the mucosa near neutrality and also prevents pepsin from acting on the stomach cells.

The cells in the gastric pits that secrete pepsin are called *chief cells*, and they secrete it as an inactive zymogen called **pepsinogen**. The extremely low pH of the stomach juices initiates the conversion of pepsinogen to pepsin by cleaving away a sequence of amino acids that masks the active site of the enzyme. Newly activated pepsin can act on other pepsinogen molecules to activate them, creating a positive feedback process called **autocatalysis** (**Figure 51.12B**).

The cells in the gastric pits that secrete HCl are called *parietal cells*. They can secrete so much HCl—about 2 liters per day—that they can bring the pH of the stomach contents below 1, which is the same as battery acid and 10 times more acidic than pure lemon juice. This means that across their plasma membranes, gastric pits can create a H^+ concentration difference of 3 million-fold. Such a feat of transport is not seen anywhere else in the body. How do they do it? Enzymes and transporters are involved.

The enzyme carbonic anhydrase in these cells catalyzes the hydration of CO_2 to H_2CO_3 , which dissociates into H^+ and bicarbonate ion (HCO_3^-). An *antiporter* transport protein (see **Figure 6.15**) exchanges HCO_3^- for Cl^- on the blood side of the gastric pits, and an antiporter on the gastric pit side exchanges H^+ for K^+ (**Figure 51.12C**). However, this K^+ can leak out again down its concentration gradient. Thus the inward transport of K^+ acts like an endless conveyor belt moving H^+ out into the stomach lumen. Cl^- also passively leaks out of the gastric lumen side of the parietal cells to maintain electrical neutrality.

Stomach ulcers can be caused by a bacterium

The secretions of the stomach are highly corrosive to living tissues and can result in *ulcers*—places where the mucosal lining of the stomach is damaged. Stomach ulcers can lead to maladies ranging from indigestion and heartburn to gastric bleeding and

51.12 Action in the Stomach (A) The human stomach stores and breaks down ingested food. (B) Cells in the gastric glands secrete hydrochloric acid and pepsin. Both the gastric glands and the mucosa secrete mucus that protects the stomach. (C) The parietal cells can create a tremendous H^+ concentration difference by actively transporting H^+ ions produced through the catalytic action of carbonic anhydrase into the lumen of the gastric pit.

stomach cancer. It was logical to assume that all ulcers were due to actions of the stomach secretions on the stomach mucosa, and that stress and lifestyle issues leading to excess stomach secretions (especially HCl) were the major causes of ulcers. This view led the pharmaceutical industry to develop a plethora of drugs to decrease stomach acid production, which became “billion dollar drugs” because they were prescribed so widely. What seemed like the simplest fact in gastrointestinal medicine, however, was turned on its head by the work of two Australian researchers. Their work is a perfect example of the application of Koch’s postulates (see Section 26.6) for the proof that a microorganism causes a disease (**Figure 51.13**).

In 1982, pathologist Robin Warren observed an unknown bacterium in biopsies from the stomachs of patients with ulcers. In a study of 100 patients, he and Barry Marshall of the University of Western Australia found that the bacterium was always present in the patients with ulcers. They isolated the bacterium, which they named *Helicobacter pylori*, and grew it in culture. Having thus satisfied Koch’s first two postulates (microbe shown to be present in all instances of the disease, and isolating the microbe from diseased tissue), they turned to the last two, as described in Figure 51.13. Marshall actually drank a flask of the cultured bacteria (don’t try this at home) and developed a pre-ulcerous condition that was subsequently cured with antibiotic. Their research showed not only that *H. pylori* causes stomach ulcers but that ulcer patients can be cured with antibiotics.

The medical profession was so certain that no microorganisms could live in the stomach and that stomach acid was the cause of ulcers that at first Warren and Marshall’s findings were resisted

and even ridiculed. But in 2005 they received the Nobel Prize in Medicine for their important discovery, and antibiotic therapy is now a primary treatment for stomach ulcers worldwide.

Drugs that decrease stomach acid production are still important ulcer medications for several reasons. Once a person has an ulcer, stomach acid exacerbates it. In addition, in many individuals the lower esophageal sphincter muscle (see Figure 51.12A) is inadequate to prevent acid from entering the esophagus, resulting in irritations and lesions there.

The stomach gradually releases its contents to the small intestine

Contractions of the smooth muscles in the walls of the stomach churn its contents, thoroughly mixing them with the stomach secretions. The acidic, fluid mixture of gastric juice and partly digested food in the stomach is called **chyme**. A few substances can be absorbed across the stomach wall, including alcohol (hence its

Marshall and Warren set out to satisfy Koch's postulates:

Test 1

The microorganism must be present in every case of the disease.

Results: Biopsies from the stomachs of many patients revealed that the bacterium was always present if the stomach was inflamed or ulcerated.

Test 2

The microorganism must be cultured from a sick host.

Results: The bacterium was isolated from biopsy material and eventually grown in culture media in the laboratory.

Test 3

The isolated and cultured bacteria must be able to induce the disease.

Results: Marshall was examined and found to be free of bacteria and inflammation in his stomach. After drinking a pure culture of the bacterium, he developed stomach inflammation (gastritis).

Test 4

The bacteria must be recoverable from the infected volunteers.

Results: Biopsy of Marshall's stomach 2 weeks after he ingested the bacteria revealed the presence of the bacterium, now christened *Helicobacter pylori*, in the inflamed tissue.

Conclusion

Antibiotic treatment eliminated the bacteria and the inflammation in Marshall. The experiment was repeated on healthy volunteers, and many patients with gastric ulcers were cured with antibiotics. Thus Marshall and Warren demonstrated that the stomach inflammation leading to ulcers is caused by *H. pylori* infections in the stomach.

rapid effects), aspirin, and caffeine, but even these substances are absorbed in rather small quantities from the stomach.

Contractions of the stomach walls push the chyme toward the bottom of the stomach. These waves of contractions cause the pyloric sphincter to relax briefly so that little squirts of the chyme can enter the small intestine. In this manner, the human stomach empties itself gradually over a period of approximately 4 hours. This slow introduction of food into the small intestine enables it to work on a little material at a time.

Most chemical digestion occurs in the small intestine

In the **small intestine**, the digestion of carbohydrates and proteins continues, and the digestion of fats and absorption of nutrients begin. The small intestine takes its name from its diameter; it is in fact a very large organ, about 6 meters long in an adult human. Given its length, and because of the folds, villi, and microvilli of its lining, its inner surface area is roughly the size of a tennis court. Across this surface, the small intestine absorbs all the nutrient molecules derived from food.

The small intestine of humans has three sections. The initial section (about 25 cm long) is called the **duodenum** and is the site of most digestion; the **jejunum** and the **ileum** (together about 600 cm) carry out 90 percent of the absorption of nutrients (see Figure 51.9).

Helicobacter pylori

51.13 Satisfying Koch's Postulates Marshall and Warren showed that ulcers are caused not by the action of stomach acid but by infection with the bacterium *Helicobacter pylori*.

Digestion in the small intestine requires many specialized enzymes, as well as several other secretions. Two accessory organs that are not part of the digestive tract—the liver and the pancreas—produce many of these secretions and deliver them to the lumen of the intestine through ducts.

LIVER The liver synthesizes **bile salts** from cholesterol and secretes them as **bile**. Bile includes bile salts and other substances, such as phospholipids and bilirubin (the breakdown product of hemoglobin). Bile flows from the liver through the **hepatic duct**. A side branch off the hepatic duct called the **cystic duct** goes to the **gallbladder**, where it is stored. Below this junction, the hepatic duct is called the **common bile duct**. Before it reaches the duodenum, it is joined by the **pancreatic duct** (**Figure 51.14**).

51.14 Ducts of the Gallbladder and Pancreas Bile produced in the liver leaves the liver via the hepatic duct. Branching off this duct is the gallbladder, which stores bile. Below the gallbladder, the hepatic duct is called the common bile duct and is joined by the pancreatic duct before entering the duodenum.

Fat entering the duodenum stimulates cells of the duodenal epithelium to release the hormone **cholecystokinin (CCK)**, which in turn stimulates the walls of the gallbladder to contract rhythmically. As a result, bile is squeezed out of the gallbladder and through the cystic duct to the common bile duct. A small sphincter at the junction of the common bile duct with the duodenum, the *sphincter of Oddi*, relaxes in response to waves of peristalsis and allows squirts of bile to enter the duodenal lumen.

To understand the role of bile in fat digestion, think of an oil and vinegar salad dressing. The oil, which is hydrophobic, tends to aggregate in large globules. For that reason, many salad dressings include an *emulsifier*—something that prevents oil droplets from aggregating. Mayonnaise, for example, is oil and vinegar with egg yolk added as an emulsifier. Bile contains salts that emulsify fats in the chyme and thereby greatly enlarge the surface area of the fats exposed to the **lipases**—the enzymes that digest fats. One end of each bile salt molecule is lipophilic (soluble in fat), and the other end is hydrophilic (soluble in water). The lipophilic ends of bile molecules merge with the fat droplets, leaving their hydrophilic ends sticking out. As a result, bile salts prevent the fat droplets from sticking together. The very small fat particles that result are called **micelles** (Figure 51.15A).

PANCREAS The **pancreas** is a large gland that lies just behind and below the stomach (see Figures 51.9 and 51.14). It is both an endocrine gland (secreting hormones into the interstitial fluid; see Section 41.1) and an exocrine gland (secreting digestive juices through the pancreatic duct to the gut lumen). The exocrine tissues of the pancreas produce a host of digestive enzymes, including lipases, amylases, proteases, and nucleases (Table 51.3). As in the stomach, the protease enzymes are released as zymogens; otherwise, they would digest the pancreas and its ducts before they ever reached the duodenum. Once in the duodenum, one of these zymogens is activated by an enzyme called *enterokinase* (secreted by cells lining the duodenum) to produce the active protease **trypsin**. Active trypsin can cleave other zymogens to release more active trypsin, as well as activate other proteases as well. This activation process is similar to the activation of pepsinogen by low pH in the stomach.

The mixture of zymogens produced by the pancreas can be dangerous if the pancreatic duct is blocked or if the pancreas is injured by infection or physical trauma such as a blow to the abdomen. A few activated trypsin molecules can initiate a chain reaction of enzyme activity that digests the pancreas (a condition called *pancreatitis*), destroying both its endocrine and exocrine functions.

51.15 Digestion and Absorption of Fats (A) Dietary fats are broken up by bile into small micelles that present a large surface area to lipases. (B) The products of fat digestion are absorbed by intestinal mucosal cells, where they are resynthesized into triglycerides and exported to lymphatic vessels.

The pancreas also produces a secretion rich in bicarbonate ions (HCO_3^-). Bicarbonate ions are alkaline (basic) and neutralize the acidic pH of the chyme that enters the duodenum from the stomach. Intestinal enzymes function best at a neutral or slightly alkaline pH.

Nutrients are absorbed in the small intestine

The final step in digesting proteins and carbohydrates and absorbing their components occurs among the microvilli. Mucosal epithelial cells produce peptidases that cleave small peptides into absorbable amino acids. These epithelial cells also produce the enzymes maltase, lactase, and sucrase, which cleave the common disaccharides into absorbable monosaccharides—glucose, galactose, and fructose. There is also some lipase activity for fat digestion.

Many humans stop producing the enzyme lactase in childhood and thereafter have difficulty digesting lactose (the sugar in milk). Lactose is a disaccharide and cannot be absorbed without being cleaved into its constituents, glucose and galactose. Unabsorbed lactose is metabolized by bacteria in the large intestine, causing gas, diarrhea, and abdominal cramps.

The mechanisms by which cells of the intestinal epithelium absorb nutrients and inorganic ions are diverse and include dif-

TABLE 51.3

Major Digestive Enzymes of Humans

SOURCE/ENZYME	ACTION
SALIVARY GLANDS	
Salivary amylase	Starch → Maltose
STOMACH	
Pepsin	Proteins → Peptides; autocatalysis
PANCREAS	
Pancreatic amylase	Starch → Maltose
Lipase	Fats → Fatty acids and glycerol
Nuclease	Nucleic acids → Nucleotides
Trypsin	Proteins → Peptides; zymogen activation
Chymotrypsin	Proteins → Peptides
Carboxypeptidase	Peptides → Shorter peptides and amino acids
SMALL INTESTINE	
Aminopeptidase	Peptides → Shorter peptides and amino acids
Dipeptidase	Dipeptides → Amino acids
Enterokinase	Trypsinogen → Trypsin
Nuclease	Nucleic acids → Nucleotides
Maltase	Maltose → Glucose
Lactase	Lactose → Galactose and glucose
Sucrase	Sucrose → Fructose and glucose

fusion, facilitated diffusion, osmosis, active transport, and co-transport. Many inorganic ions such as sodium, calcium, and iron are actively transported by these cells. For example, active Na^+ transporters exist on the basal and lateral sides of the epithelial cells. They maintain a low concentration of Na^+ in those cells so that Na^+ can diffuse in from the chyme in the intestinal lumen. About 30 grams of Na^+ are transported this way every day, and Cl^- follows.

The transport of Na^+ and other ions is also important for water absorption because it creates an osmotic concentration gradient. At least 7 to 8 liters of water per day move through the spaces between the epithelial cells in response to this osmotic gradient. Because the water moves through *spaces* between the cells and not through the cells themselves, it can carry with it nutrients that are in solution—a transport mechanism called *solvent drag*.

Many different kinds of transport proteins exist in the epithelial cell membranes. Some, such as the transport protein for fructose, only facilitate diffusion, and that requires a concentration gradient. This mechanism works for fructose because once fructose enters the cell it is converted to glucose. Thus the concentration of fructose in the cell is always low and the concentration gradient is maintained. Transport proteins known as *symporters* (see Figure 6.15) exploit the concentration gradient of Na^+ between the inside and outside of the cell, which is maintained by the Na^+/K^+ ATPase common to all cells. Symporters combine the transport of Na^+ and another molecule, such as glucose, galactose, or an amino acid. As Na^+ is pulled down its con-

centration gradient into the cell, the “hitchhiking” molecules are carried along with it.

The absorption of the products of fat digestion is relatively simple. Triglycerides are hydrolyzed to diglycerides, monoglycerides, and fatty acids, all of which are lipid-soluble and thus able to pass through the plasma membranes of the microvilli. In the intestinal epithelial cells, these molecules are resynthesized into triglycerides, combined with cholesterol and phospholipids, and coated with protein to form water-soluble **chylomicrons** (Figure 51.15B). Rather than enter the blood directly, chylomicrons pass into blind-ended lymph vessels called **lacteals** that are inside each villus (see Figure 51.8). They then flow through the lymphatic system, entering the bloodstream through the thoracic ducts at the base of the neck. After a meal rich in fats, chylomicrons can be so abundant in the blood that they give the plasma a milky appearance. Chylomicrons deliver their triglyceride and cholesterol cargo as they circulate through tissues.

The bile salts that emulsify fats are not absorbed along with the monoglycerides, diglycerides, and the fatty acids, but are shuttled back and forth between the gut contents and the microvilli. In the ileum, bile salts are actively reabsorbed and returned to the liver via the bloodstream.

Absorbed nutrients go to the liver

Blood leaving the digestive tract flows to the liver in the *hepatic portal vein*. This large vein delivers the blood to small spaces called sinusoids between groups of liver cells. These cells absorb the nutrients coming from the digestive tract and either store them or convert them to molecules the body needs. Glucose, sucrose, and fructose are used to synthesize glycogen. Amino acids are used to build proteins. Lipids from the chylomicrons are either stored as triglycerides or used to make *lipoproteins*, which are released by the liver and deliver the triglycerides and cholesterol to other tissues (see Section 51.4).

Water and ions are absorbed in the large intestine

The motility of the small intestine gradually pushes its contents into the *large intestine*, or **colon**. Most of the available nutrients have been removed from the chyme that enters the colon, but it contains a lot of water and inorganic ions.

The colon absorbs water and ions, producing semisolid feces from the chyme it receives from the small intestine. Feces are stored in the rectum of the colon until they are eliminated. Absorption of too much water from the colon can cause *constipation*. The opposite condition, *diarrhea*, results if too little water is absorbed; in this case, water in the colon is excreted with the feces. The excessive diarrhea caused by diseases such as cholera can produce such rapid loss of water and electrolytes that death can occur in hours.

Herbivores rely on microorganisms to digest cellulose

As the primary component of plant cell walls, cellulose is the principal component of the food of herbivores. Most herbivores, however, cannot produce *cellulases*—enzymes that hydrolyze

51.16 A Ruminant's Stomach Bison, like their relatives domestic cattle, have a specialized stomach with four compartments that enables them to obtain energy from coarse plant material through bacterial fermentation of the otherwise indigestible plant material. The bacteria themselves become an important source of nutrition.

can digest and absorb the nutrients that would otherwise be lost. In humans, the cecum has become the vestigial **appendix**, which serves no digestive function.

51.3 RECAP

The vertebrate gastrointestinal system is a tubular gut that is adapted to ingest food, fragment it, digest it, and absorb nutrients. Peristalsis moves food through the gut. Digestion and absorption of nutrients occur mostly in the small intestine; water and ions are absorbed in the large intestine.

- What digestive functions occur in the mouth and stomach? [See p. 1079 and Figure 51.12](#)
- How do bile salts assist in the digestion of fats? [See p. 1082 and Figure 51.15](#)
- Describe how symporters drive the absorption of nutrients. [See p. 1083](#)

cellulose. Exceptions include silverfish (insects that eat books and stored papers), earthworms, and shipworms. From termites to cattle, herbivores rely on microorganisms in their digestive tracts to digest cellulose.

The stomachs of **ruminants** (cud chewers) such as cattle are large, four-chambered organs that take advantage of their endosymbiotic microorganisms ([Figure 51.16](#)). The first two chambers, the **rumen** and the **reticulum**, are packed with microorganisms that break down cellulose by fermentation. The ruminant periodically regurgitates the contents of the rumen (the *cud*) into the mouth for rechewing. When swallowed again, the vegetal fibers present more surface area to the microorganisms. The microorganisms metabolize cellulose and other nutrients to simple fatty acids, which become nutrients for their host.

Enormous numbers of microorganisms leave the rumen along with the partially digested food. This mass is concentrated by water absorption in the **omasum** before it enters the true stomach, the **abomasum**, where the microorganisms are killed by secreted hydrochloric acid, digested by proteases, and passed on to the small intestine for further digestion and absorption. A cow derives more than 100 grams of protein per day from digestion of its endosymbiotic microorganisms. The rate of multiplication of microorganisms in the rumen offsets their loss, so a well-balanced, mutually beneficial relationship is maintained.

Some mammalian herbivores have a microbial fermentation chamber called a **cecum** extending from the large intestine. An example is the rabbit (see [Figure 51.7](#)). Since the cecum empties into the large intestine, absorption of some nutrients produced by the microorganisms is inefficient, because of the large intestine's limited surface area. Such species frequently produce two kinds of feces—ones that are pure waste and ones that contain cecal material. In a behavior known as **coprophagy**, these species reingest the cecal feces directly from the anus so they

The steps included in ingestion and digestion of food—from fragmentation in the mouth to the digestive processes in the gastrointestinal tract—make the nutrients in food available for absorption and ultimately for metabolism. Let's look at how the processes of digestion are controlled and how nutrients are handled by the body once food has been digested.

51.4 How Is the Flow of Nutrients Controlled and Regulated?

The vertebrate gut is an assembly line in reverse—a *disassembly* line. As with a standard assembly line, the control and coordination of the sequential processes of digestion is critical. Both neuronal and hormonal controls govern these processes. Once the products of digestion are absorbed, their availability to the cells of the body must also be controlled.

You have certainly experienced salivation at the sight or smell of food. That response is an *unconscious reflex*, as is swallowing. Many such autonomic reflexes coordinate activity in different regions of the digestive tract. For example, the introduction of food into the stomach stimulates increased activity in the colon, which can lead to defecation.

As we already mentioned, the digestive tract has an intrinsic nervous system. Neuronal messages can travel from one region of the digestive tract to another without being processed by the CNS. One function of the gut's nervous system is coordinating the movement of food through the gut. Of course, this intrinsic nervous system communicates information to the CNS and receives input from the CNS, but its most important role is to coordinate actions throughout the digestive tract. In spite of this marvelous intrinsic nervous system, however, much of the control and regulation of the digestive system and nutrient management involves hormonal mechanisms.

Hormones control many digestive functions

Several hormones control the activities of the digestive tract and its accessory organs (**Figure 51.17**). The first hormone ever discovered came from the duodenum; it was called **secretin** because it causes the pancreas to secrete digestive juices. We now know that secretin is only one of several hormones that control pancreatic secretion; specifically, secretin stimulates the pancreas to secrete a solution rich in bicarbonate ions.

The stimulus that causes the duodenum to release secretin is low pH—the arrival of acidic chyme from the stomach. Similarly, the presence of fats and proteins in the chyme stimulates the release of cholecystokinin (CCK), the hormone mentioned earlier that stimulates the gallbladder to release bile. CCK also stimulates the pancreas to release digestive enzymes. Both CCK and secretin slow the movements of the stomach, which slows the delivery of chyme into the small intestine, allowing more complete digestion in the duodenum.

The presence of food in the stomach stimulates cells in the lower region of the stomach to secrete a hormone called **gastrin**. Gastrin returns to the stomach in the blood and stimulates the secretion of digestive juices and also the movements of the stomach. Gastrin release begins to be inhibited when the pH of the stomach contents falls below 3—an example of negative feedback.

Most animals do not eat continuously, so they can be either in an **absorptive state** (food in the gut) or in a **postabsorptive state** (no food in the gut). Nutrient requirements for energy metabolism and biosynthesis are continuous, however. Thus, nutrient traffic must be controlled so that reserves accumulate in the liver, muscle, and adipose (fat) tissue while the animal is in the absorptive state and are used appropriately during the postabsorptive state.

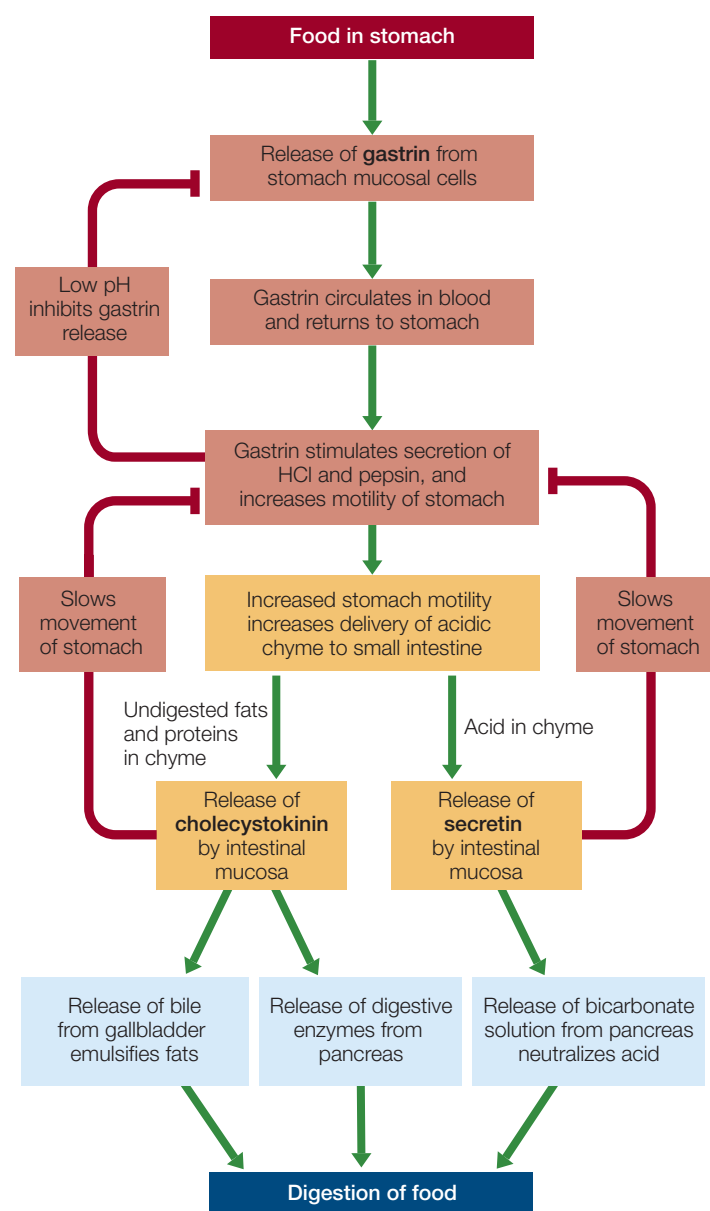

The liver directs the traffic of the molecules that fuel metabolism

When fuel molecules are abundant in the blood, the liver stores them in the form of glycogen and fats. The liver also synthesizes

blood plasma proteins from circulating amino acids. When fuel molecule levels in the blood decline, the liver taps its reserves and delivers nutrients into the blood.

The liver has an enormous capacity to interconvert fuel molecules. Liver cells can convert monosaccharides into either glycogen or fats, and vice versa. The liver can also convert certain amino acids and some other molecules, such as pyruvate and lactate, into glucose—a process termed *gluconeogenesis* (see Section 9.5). The liver is also the major controller of fat metabolism through its production of lipoproteins. A **lipoprotein** is a particle made up of a core of hydrophobic fat and cholesterol with a covering of hydrophilic protein that allows it to be suspended in water.

LIPOPROTEINS: THE GOOD, THE BAD, AND THE UGLY Lipoproteins move fats, the most abundant fuel reserve in the body, from sites of storage to sites of use. We saw in the previous section how,

51.17 Hormones Control Digestion The hormones gastrin, cholecystokinin, and secretin are involved in feedback loops that control the sequential processing of food in the digestive tract. Red lines indicate inhibitory actions; green lines indicate stimulatory actions.

in the intestine, bile solves the problem of processing hydrophobic fats in an aqueous medium. The transport of fats in the circulatory system presents the same problem, and lipoproteins provide the solution.

The chylomicrons (see p. 1083) produced by the mucosal cells of the intestine are the largest lipoprotein particles in the blood. As the circulation carries chylomicrons through the liver and adipose tissue, lipoprotein lipases begin to break them down, and their triglyceride and cholesterol cargo is absorbed into the liver or fat cells.

Lipoproteins other than chylomicrons are synthesized in the liver. These lipoproteins can be classified according to their density. Fat has a low density (it floats in water) and protein has a high density, so the greater the fat-to-protein ratio in the lipoprotein, the lower its density.

- **High-density lipoproteins (HDLs)** remove cholesterol from tissues and carry it to the liver, where it can be used to synthesize bile. HDL consists of about 50% protein, 35% lipids, and 15% cholesterol. These are the “good” lipoproteins, and their levels are higher in people who exercise and are fit.
- **Low-density lipoproteins (LDLs)** transport cholesterol around the body for use in biosynthesis and for storage. LDL consists of about 25% protein, 25% lipids, and 50% cholesterol. These are the “bad” lipoproteins associated with a high risk for cardiovascular disease.
- **Very low-density lipoproteins (VLDLs)** contain mostly triglyceride fats, which they transport to fat cells in adipose tissues around the body. VLDL consists of about 2% protein, 94% lipids, and 3% cholesterol. These are the “ugly,” as they are associated with excessive fat deposition as well as a high risk for cardiovascular disease.

INSULIN AND GLUCAGON CONTROL FUEL METABOLISM During the absorptive state, blood glucose levels rise as carbohydrates are digested and absorbed (**Figure 51.18**). During this time, β cells of the pancreas release insulin, which plays a major role in directing glucose to where it will be used or stored. The actions of insulin vary in different tissues, but they are all aimed at promoting the use of glucose for metabolic fuel and getting the excess into storage as glycogen or fat.

Glucose enters cells by diffusion facilitated by glucose transporters. However, the glucose transporters in resting skeletal muscle and adipose tissues are normally sequestered in cytoplasmic vesicles until insulin binds its receptors on the cell surface and triggers the insertion of transporters into the plasma membrane. In adipose cells, insulin inhibits lipase and promotes fat synthesis from glucose. In the liver, insulin activates an enzyme that phosphorylates glucose as it enters the cell so it cannot diffuse back out again, enhancing the overall diffu-

sion of glucose into the cells. In liver cells, insulin also activates the enzymes that catalyze the synthesis of glycogen.

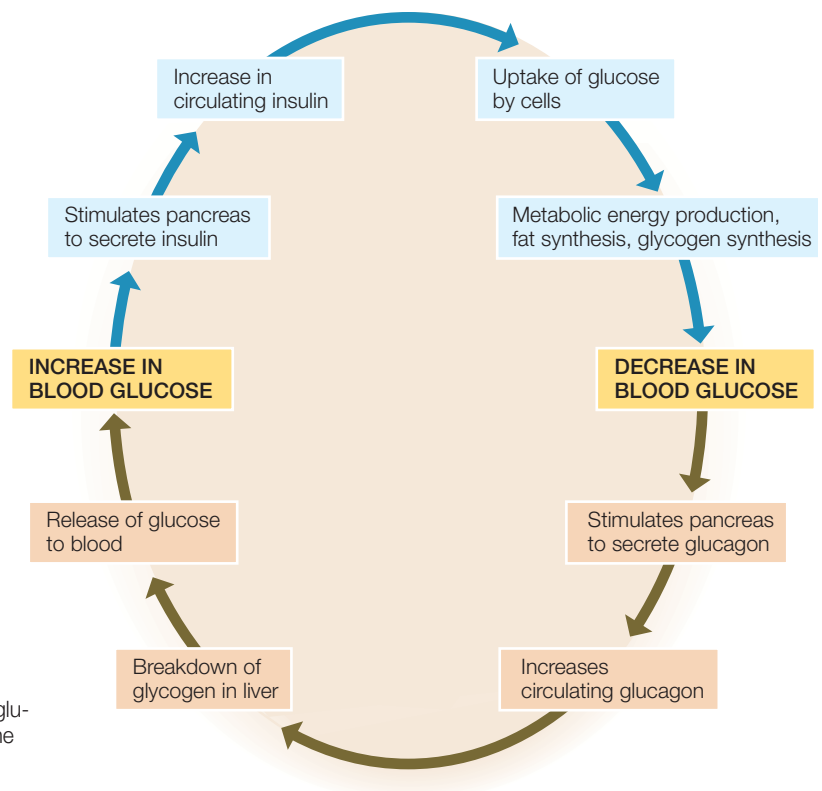

During the postabsorptive state, a fall in blood glucose decreases the release of insulin, and the uptake of glucose by most cells is curtailed (see **Figure 51.18**). To maintain blood glucose levels, liver cells break down their stored glycogen, which releases glucose into the blood. The liver and adipose tissues supply fatty acids to the blood, and most cells preferentially use fatty acids as their metabolic fuel.

One tissue that does not switch fuel sources when an animal is postabsorptive is the nervous system. The cells of the nervous system require a constant supply of glucose, and they can use other fuels to a very limited extent. Most neurons do not require insulin to absorb glucose from the blood, but they do need an adequate glucose concentration gradient to drive the facilitated diffusion of glucose across their plasma membranes. Therefore it is critical that blood glucose levels are maintained when an animal is postabsorptive. The overall dependence of neural tissues on glucose, and their requirement for constant blood glucose levels, are the reasons it is so important for other cells of the body to shift to fat metabolism during the postabsorptive state.

The metabolism of fuel molecules during the postabsorptive state is mostly controlled by the lack of insulin, but if blood glucose falls below a certain level, another pancreatic hormone, **glucagon**, is called into play. Glucagon’s effect is opposite that of insulin: it stimulates liver cells to break down glycogen and to carry out gluconeogenesis. Thus, under the influence of glucagon, the liver produces glucose and releases it into the blood.

GO TO Animated Tutorial 51.2 • Insulin and Glucose Regulation

51.18 Regulating Glucose Levels in the Blood Insulin (blue) and glucagon (brown) interactions maintain the homeostasis of circulating glucose. It is important for blood glucose to remain stable because it is the essential source fuel for the nervous system.

Regulating food intake is important

Obesity is a major health issue in the United States. A simple rule—take in fewer calories than your body burns while eating a balanced diet—should solve the problem, but it doesn't. Why? As we noted at the beginning of this chapter, lifestyle plays a major role in obesity, and genetic and regulatory factors “weigh in” as well.

The amount of food an animal eats is governed by its sensations of hunger and satiety. These sensations are influenced by the hypothalamus (see Section 41.2). If a region in the middle of the hypothalamus of rats (the *ventromedial hypothalamus*) is experimentally damaged, the animals will increase their food intake and become obese. If a different region, called the lateral hypothalamus, is damaged, they will decrease their food intake and become thin. In both cases, the rats eventually reach a new equilibrium body weight, which they maintain. Thus, regulation is maintained, but the set point is changed. Other brain regions have also been implicated in control of hunger and satiety.

In Section 40.1 we noted that regulation involves feedback information and a means of comparing that information with a set point. Criteria for a negative feedback signal for food intake include:

- Levels of the signal in the circulation reflect body energy reserves.
- The signal crosses the blood–brain barrier.
- Presence of the signal in the brain decreases food intake and body mass.
- Blocking the signal's actions in the brain results in increased food intake and gain of body mass.

Two molecules—insulin and leptin—satisfy these criteria. We have already discussed the roles of insulin in fuel management (see Figure 51.18); it may also have a role in signaling the hypothalamus about the fuel stores of the body.

The protein **leptin** (Greek *leptos*, “thin”) was discovered in a strain of mice that eat enormous amounts of food and become obese. Experiments revealed this trait to be due to a recessive allele of a single gene, which they designate *ob*. It was subsequently learned that the wild-type *Ob* gene codes for leptin. The obese mice carried two copies of the recessive allele for the leptin gene and thus were designated *ob/ob*.

Leptin is a circulating hormone produced by fat cells. Receptors for leptin are found in the regions of the hypothalamus involved in controlling hunger and satiety. It seems that leptin provides feedback information to the brain about the status of the body's fat reserves. When leptin was injected into *ob/ob* mice, they ate less and lost body fat. However, a different strain of obese mice, *db/db*, did not respond to leptin injections. Further experiments revealed that *db/db* mice lacked the receptor for leptin (**Figure 51.19**).

Could leptin be used to treat human obesity? In the few obese people who do not produce leptin, injections curb appetite and facilitate weight loss. Most obese people, however, have higher than normal levels of leptin in their blood, so the likelihood is that it is their leptin receptors that are not completely functional.

INVESTIGATING LIFE

51.19 A Single-Gene Mutation Leads to Obesity in Mice

In mice the *Ob* gene codes for the protein leptin, a satiety factor that signals the brain when enough food has been consumed. The recessive *ob* allele is a loss-of-function allele, so *ob/ob* mice do not produce leptin; they do not experience satiety and become obese. The *Db* gene encodes the leptin receptor, so mice homozygous for the recessive loss-of-function allele *db*, even if they produce leptin, cannot use it and so become obese.

HYPOTHESIS Mice who cannot produce the satiety signal protein leptin will not become obese if they are able to obtain leptin from an outside source.

METHOD

1. Create two strains of genetically obese laboratory mice, one of which lacks functional leptin (genotype *ob/ob*) and one which lacks the receptor for leptin (genotype *db/db*).
2. Create parabiotic pairs by surgically joining the circulatory systems of a non-obese (wild-type) mouse with a partner from one of the obese strains.
3. Allow mice to feed at will.

Parabiotic pair

Wild-type mouse
(*Ob/ob* and *Db/ob*)

Genetically obese mouse
(either *ob/ob* or *db/db*)

RESULTS

Parabiotic *ob/ob* mice obtain leptin from the wild-type partner and lose fat. Parabiotic *db/db* mice remain obese because they lack the leptin receptor and thus the leptin they obtain from their partner has no effect.

CONCLUSION The protein leptin is a satiety signal that acts to prevent overeating and resultant obesity.

Additional feedback signals are involved in regulating food intake. A hormone called *peptide YY* comes from the gut and reduces appetite in both rodents and humans. In contrast, *ghrelin*, a hormone produced and secreted by cells in the stomach, rises before a meal and falls after a meal. Fasting causes an increase in ghrelin levels. Ghrelin binding to its receptors in the hypothalamus stimulates appetite. Ghrelin also stimulates cells in the pituitary gland to release growth hormone.

Most interesting, however, is the discovery of the central role of the enzyme AMP-activated protein kinase (AMPK) as a signal of nutrient insufficiency. When most cells are nutrient deprived, they produce AMPK, which stimulates the oxidation of substrates to replenish ATP. However, in the hypothalamus, increased levels of AMPK stimulate food intake, and lowered levels of AMPK inhibit food intake. In addition, AMPK activity in the hypothalamus is inhibited by leptin and insulin but is stimulated by ghrelin. Thus, AMPK could be a final common pathway for various signals controlling food intake.

51.4 RECAP

The major controlling factors of gut function are an intrinsic nervous system and the hormones gastrin, secretin, and cholecystokinin. Insulin is the major hormonal controller of fuel metabolism. The hypothalamus controls food intake by generating sensations of hunger and satiety influenced by feedback from blood glucose and hormones, including leptin and ghrelin.

- What are the roles of the three different classes of lipoproteins? **See pp. 1085–1086**
- By what actions does insulin promote uptake and storage of energy during the absorptive state? **See p. 1086 and Figure 51.18**
- What evidence supports the hypothesis that leptin influences satiety? **See p. 1087 and Figure 51.19**

CHAPTER SUMMARY

51.1 What Do Animals Require from Food?

- Animals are **heterotrophs** that derive their energy and molecular building blocks, directly or indirectly, from **autotrophs**.
- Carbohydrates, fats, and proteins in food supply animals with metabolic energy. A measure of the energy content of food is the **kilocalorie (kcal)**. Excess caloric intake is stored as glycogen and fat. **Review Figure 51.2**
- For many animals, food provides essential **carbon skeletons** that they cannot synthesize themselves. **Review Figure 51.4**
- Most researchers consider 8 amino acids to be essential for adult humans; some believe that infants require as many as 12 **essential amino acids** in their diet. **Macronutrients** are mineral elements needed in large quantities, **micronutrients** are needed in small amounts. **Review Figure 51.5, Table 51.1, WEB ACTIVITY 51.1**
- **Vitamins** are organic molecules that must be obtained in food. **Review Table 51.2, WEB ACTIVITY 51.2**
- **Malnutrition** results when any essential nutrient is lacking from the diet. Chronic malnutrition causes **deficiency disease**.

51.2 How Do Animals Ingest and Digest Food?

- Animals can be characterized by how they acquire nutrients: **saprobies** and **detritivores** depend on dead organic matter, **filter feeders** strain the aquatic environment for small food items, **herbivores** eat plants, and **carnivores** eat animals. Behavioral and anatomical adaptations reflect these feeding strategies. **SEE WEB ACTIVITY 51.3**
- Digestion involves the breakdown of complex food molecules into monomers that can be absorbed and utilized by cells. In most animals, digestion takes place in a tubular gut. **Review Figure 51.7**
- Absorptive areas of the gut are characterized by a large surface area produced by extensive folding and numerous **villi** and **microvilli**. **Review Figure 51.8**
- Hydrolytic enzymes break down proteins, carbohydrates, and fats into their monomeric units. To prevent the organism itself

from being digested, many of these enzymes are released as inactive **zymogens**, which become activated when secreted into the gut.

51.3 How Does the Vertebrate Gastrointestinal System Function?

- The vertebrate gut can be divided into several compartments with different functions. **Review Figure 51.9, WEB ACTIVITY 51.4**
- The cells and tissues of the vertebrate gut are organized in the same way throughout its length. The innermost tissue layer, the **mucosa**, is the secretory and absorptive surface. The **submucosa** contains blood and lymph vessels and a nerve network. External to the submucosa are two smooth muscle layers. Between the two muscle layers is another nerve network that controls the movements of the gut. **Review Figure 51.10**
- Swallowing is a reflex that pushes a bolus of food into the **esophagus**. **Peristalsis** and other movements of the gut move the bolus down the esophagus and through the entire length of the gut. Sphincters block the gut at certain locations, but they relax as a wave of peristalsis approaches. **Review Figure 51.11**
- Digestion begins in the **mouth**, where **amylase** is secreted with the saliva. Digestion of protein begins in the **stomach**, where parietal cells secrete HCl and chief cells secrete **pepsinogen**, a zymogen that becomes **pepsin** when activated by low pH and **autocatalysis**. The mucosa also secretes mucus, which protects the tissues of the gut. **Review Figure 51.12**
- In the **duodenum**, pancreatic enzymes carry out most of the digestion of food. Bile from the liver and **gallbladder** emulsify fats into micelles. Bicarbonate ions from the **pancreas** neutralize the pH of the **chyme** entering from the stomach to produce an environment conducive to the actions of pancreatic enzymes such as **trypsin**. **Review Figure 51.14 and Table 51.3**
- Final enzymatic cleavage of polypeptides and disaccharides occurs among the microvilli of the intestinal mucosa. Amino acids, monosaccharides, and inorganic ions are absorbed by the microvilli. Specific transporter proteins are sometimes involved. Symporters often power the active transport of nutrients.

- Fats broken down by **lipases** are absorbed mostly as monoglycerides and fatty acids and are resynthesized into triglycerides within cells. The triglycerides are combined with cholesterol and phospholipids and coated with protein to form **chylomicrons**, which pass out of the mucosal cells and into lymphatic vessels in the submucosa. **Review Figure 51.15, ANIMATED TUTORIAL 51.1**
- Water and ions are absorbed in the large intestine as waste matter and consolidated into **feces**, which are periodically eliminated.
- Microorganisms in some compartments of the gut digest materials that their host cannot. **Review Figure 51.16**

51.4 How Is the Flow of Nutrients Controlled and Regulated?

- Autonomic reflexes coordinate activity of the digestive tract, which has an intrinsic nervous system that can act independently of the CNS.
- The actions of the stomach and small intestine are largely controlled by the hormones **gastrin**, **secretin**, and **cholecystokinin**. **Review Figure 51.17**
- The liver plays a central role in directing the traffic of fuel molecules. In the **absorptive state**, the liver takes up and stores fats and carbohydrates, converting monosaccharides to glycogen or fats. The liver also takes up amino acids and uses them to produce blood plasma proteins, and can engage in gluconeogenesis.
- Fat and cholesterol are shipped out of the liver as **low-density lipoproteins**. **High-density lipoproteins** act as acceptors of cholesterol and are believed to bring fat and cholesterol back to the liver.
- Insulin largely controls fuel metabolism during the absorptive state and promotes glucose uptake as well as glycogen and fat synthesis. In the **postabsorptive state**, lack of insulin blocks the uptake and utilization of glucose by most cells of the body except neurons. If blood glucose levels fall, **glucagon** secretion increases, stimulating the liver to break down glycogen and release glucose to the blood. **Review Figure 51.18, ANIMATED TUTORIAL 51.2**
- Food intake is governed by sensations of hunger and satiety, which are determined by brain mechanisms responding to feedback signals such as insulin, **leptin**, and **ghrelin**. **Review Figure 51.19**

SELF-QUIZ

- Most of the metabolic energy needed by a bird for a long-distance migratory flight is stored as
 - glycogen.
 - fat.
 - protein.
 - carbohydrates.
 - ATP.
- Which statement about essential amino acids is true?
 - They are not found in vegetarian diets.
 - They are stored by the body until they are needed.
 - Without them, one is undernourished.
 - All animals require the same ones.
 - Humans can acquire all of theirs by eating milk, eggs, and meat.
- Which statement about vitamins is true?
 - They are essential inorganic nutrients.
 - They are required in larger amounts than are essential amino acids.
 - Many serve as coenzymes.
 - Vitamin D can be acquired only by eating meat or dairy foods.
 - When vitamin C is eaten in large quantities, the excess is stored in fat for later use.
- The digestive enzymes of the small intestine
 - do not function best at a low pH.
 - are produced and released in response to circulating secretin.
 - are produced and released under neural control.
 - are all secreted by the pancreas.
 - are all activated by an acidic environment.
- Which statement about nutrient absorption by the intestinal mucosal cells is true?
 - Carbohydrates are absorbed as disaccharides.
 - Fats are absorbed as fatty acids and monoglycerides.
 - Amino acids move across the plasma membrane only by diffusion.
 - Bile transports fats across the plasma membrane.
 - Most nutrients are absorbed in the duodenum.
- Chylomicrons are like the tiny micelles of dietary fat in the lumen of the small intestine in that both
 - are coated with bile.
 - are lipid soluble.
 - travel through the lymphatic system.
 - contain triglycerides.
 - are coated with lipoproteins.
- Microbial fermentation in the gut of a cow
 - produces fatty acids as a major nutrient for the cow.
 - occurs in specialized regions of the small intestine.
 - occurs in the cecum, from which food is regurgitated, chewed again, and swallowed into the true stomach.
 - produces methane as a major nutrient.
 - is possible because the stomach wall does not secrete hydrochloric acid.
- Which of the following is stimulated by cholecystokinin?
 - Stomach motility
 - Release of bile
 - Secretion of hydrochloric acid
 - Secretion of bicarbonate ions
 - Secretion of mucus
- During the absorptive state,
 - breakdown of glycogen supplies glucose to the blood.
 - glucagon secretion is high.
 - the number of circulating lipoproteins is low.
 - glucose is the major metabolic fuel.
 - the synthesis of fats and glycogen in muscle is inhibited.
- During the postabsorptive state,
 - glucose is the major metabolic fuel.
 - glucagon stimulates the liver to produce glycogen.
 - insulin facilitates the uptake of glucose by brain cells.
 - fatty acids constitute the major metabolic fuel.
 - liver functions slow down because of low insulin levels.

FOR DISCUSSION

1. Several currently popular diet books recommend high fat and protein intake and low carbohydrate intake as a means of losing body mass. What is the rationale for a high-fat and high-protein diet, and what health issues should be considered when someone considers going on such a diet?
2. Carnivores generally have more dietary vitamin requirements than herbivores do. Why?
3. It is said that the most important hormonal control of fuel metabolism in the postabsorptive state is the lack of insulin. Explain.
4. Why is obstruction of the common bile duct so serious? Consider in your answer the multiple functions of the pancreas and the way in which digestive enzymes are processed.
5. Trace the history of a fatty acid molecule from a slice of cheese pizza to a plaque on a coronary artery. Into what possible forms and structures might it have been converted as it passed through the body? Describe a direct and an indirect route it could have taken.

ADDITIONAL INVESTIGATION

You learned about brown fat in Chapter 40. This adipose tissue has lots of mitochondria and a rich blood supply and is found in many newborn mammals and cold-adapted mammals such as hibernators. The function of brown fat is to produce heat through uncoupling of oxidative phosphorylation and therefore the metabolism of lipids without the production of ATP. It has been thought for a long time that adult humans do not have

brown fat, but recent studies have indicated that they do. It has further been hypothesized that the amount of brown fat an individual has is highly variable, and that this might explain why some individuals are more resistant to weight gain than others. Keeping in mind that brown fat is activated by the sympathetic nervous system, how would you investigate the possible role of brown fat in body weight control?

52

Salt and Water Balance and Nitrogen Excretion

Blood, sweat, and tears

Blood, sweat, and tears taste salty because they have ionic concentrations similar to those of the interstitial fluids that bathe the cells of the body. The volume and composition of the interstitial fluids must remain within certain limits and be kept relatively free of wastes. Maintaining homeostasis of the interstitial fluids is the job of the excretory system, and it can be challenging. Sometimes it requires getting rid of excess fluids, and at other times it requires conserving fluids.

The nature of the challenge depends on the environment of the animal and its lifestyle. Some desert animals rarely if ever encounter free water; they must be able to live their entire lives without drinking. All animals derive water from the metabolism of food, but to survive on that amount of water, desert animals must conserve it to an

exceptional degree. Accordingly, they excrete wastes that are extremely concentrated. Insects excrete semisolid wastes, and desert rodents excrete urine that is so concentrated it forms crystals of solute. Animals that live in fresh water have the opposite problem: water continuously enters their bodies by osmosis and with the food they eat, so they must constantly bail themselves out by producing copious amounts of dilute urine while at the same time conserving the solutes their bodies need.

The physiological adaptations animals have to maintain salt and water balance through excretion and conservation are remarkably flexible. Consider, for example, the vampire bat, a small tropical mammal that experiences extreme conditions within minutes of each other. The vampire bat feeds on the blood of other mammals, such as goats and cattle. Landing on an unsuspecting (usually sleeping) victim, the bat uses its sharp incisor teeth to make a small incision in a blood vessel and then laps up the blood that wells out.

Blood contains lots of nutritious protein, but it consists mostly of water. Blood meals may be few and far between, so the bat must quickly consume as much as it can—up to half its body mass. To maximize its protein intake and keep its weight low enough to fly, it rapidly eliminates the water from its meal. Within minutes of starting to feed, the bat is producing a lot of very dilute urine. The warm trickle down the neck of the victim is not blood!

Blood as a Fast Food The vampire bat *Desmodus rotundus* is able to adjust its excretory physiology from water-excreting to water-conserving, depending on whether it is ingesting or digesting its blood meal.

Living without Water Many kangaroo rat species (*Dipodomys*) inhabit arid deserts, and they rarely see free water.

Once feeding ends, this high rate of water loss must stop. Now the vampire bat is digesting and metabolizing protein and must excrete large amounts of nitrogenous wastes while conserving its body water. Within minutes, the bat's excretory system switches from producing abundant, dilute urine to producing a tiny amount of highly concentrated urine. In one feeding cycle, the vampire bat rapidly transitions from an excretory physiology typical of a mammal living in an environment with abundant fresh water to that of a desert mammal that never sees water. What an amazing case of physiological flexibility!

IN THIS CHAPTER we will describe adaptations for maintaining salt and water balance and for excreting nitrogenous wastes in environments that present animals with different challenges. Using some invertebrate examples, we will review the basic mechanisms common to all animal excretory systems. We will learn about the basic anatomical unit of the vertebrate excretory system—the nephron—and how it evolved. Finally, we will consider the mechanisms that control and regulate salt and water balance in mammals.

CHAPTER OUTLINE

- 52.1** How Do Excretory Systems Maintain Homeostasis?
- 52.2** How Do Animals Excrete Nitrogen?
- 52.3** How Do Invertebrate Excretory Systems Work?
- 52.4** How Do Vertebrates Maintain Salt and Water Balance?
- 52.5** How Does the Mammalian Kidney Produce Concentrated Urine?
- 52.6** How Are Kidney Functions Regulated?

52.1 How Do Excretory Systems Maintain Homeostasis?

Controlling the volume, solute concentration, and composition of extracellular fluids are not huge problems for marine invertebrates because their extracellular fluids are very similar to seawater, and their nitrogenous wastes can simply diffuse into the surrounding seawater. The situation is different for marine vertebrates and for all freshwater and terrestrial animals because their extracellular fluids differ considerably from the external environment. These animals depend on **excretory systems** to maintain the volume, concentration, and composition of their extracellular fluids, and to excrete wastes.

Homeostasis of the extracellular fluids is critical because the concentration of solutes in them determines the water balance of the cells those fluids bathe, and the composition of the extracellular fluid influences the health and functions of all the cells of the body. Consider, for example, the importance of ion concentration gradients between the extracellular fluid and the cytoplasm of nerve and muscle cells (see Sections 45.2 and 48.1).

Water enters or leaves cells by osmosis

The volume of cells depends on whether they take up water from or lose water to the extracellular fluids. The movement of water across cell plasma membranes depends on differences in solute concentration on the two sides of the membrane and the permeability of the membrane. This is the process of osmosis, which we discuss in Sections 6.3 and 35.1. If the solute concentration of the extracellular fluid is less than that of the cytoplasm, water moves into the cells, causing them to swell and possibly burst. If the solute concentration of the extracellular fluid is greater than that of the cytoplasm, the cells lose water and shrink. Thus the solute concentration of the extracellular fluid affects both the volume and the solute concentration of the cells.

Animal physiologists use the term **osmolarity** in discussing osmosis. The osmolarity of a solution is the number of moles of osmotically active solutes per liter of solvent. Thus, a 1 molar solution of glucose is also a 1 osmolar (1 osmole per liter) solution, but a 1 molar solution of sodium chloride (NaCl) is a 2 osmolar solution, because each NaCl molecule dissociates into two osmotically active ions.

To achieve cellular water balance, animals must maintain the osmolarity of their extracellular fluid within an appropriate range. In addition, they must maintain an appropriate solute

composition by saving some substances (reabsorption) and eliminating others (secretion). To accommodate these needs, most animals have excretory systems.

Excretory systems control extracellular fluid osmolarity and composition

Excretory systems control the osmolarity and composition of the extracellular fluids by excreting solutes that are present in excess (such as NaCl when we eat lots of salty food) and conserving solutes that are valuable or in short supply (such as glucose and amino acids). Excretory systems also eliminate the toxic waste products of protein metabolism. The output of the excretory system is called **urine**.

Three basic processes are common to a wide variety of animal excretory systems: filtration, secretion, and reabsorption. Extracellular fluid is filtered to produce a filtrate that contains no cells or large molecules, such as proteins. In animals with a closed circulatory system, the blood plasma is usually filtered from capillaries into associated tubules. The walls of the capillaries and of the tubules are the filter, and the filtration is driven by blood pressure. As the filtrate flows through the tubules, its composition and concentration are modified through processes of secretion and reabsorption to form the urine that leaves the body.

The processing of the filtrate into urine involves movement of water into and out of the tubules. There are no mechanisms for the active transport of water. The movement of water is due either to a pressure difference (filtration) or to a difference in solute concentration (osmosis). Water always flows down a pressure gradient or up a solute concentration gradient.

Animals can be osmoconformers or osmoregulators

Animals that live in marine, freshwater, or terrestrial environments face different salt and water balance problems. In the terrestrial environment, salts and water can be scarce and usually must be conserved by excretory systems. In the freshwater environment, water is plentiful but salts are scarce. Freshwater animals have to conserve salts and excrete the water that continuously invades their bodies through osmosis.

In contrast to fresh water, ocean water has a high osmolarity—over 1,000 milliosmoles/liter (mosm/l). Most marine invertebrates equilibrate their extracellular fluid osmolarity with the ocean water and are therefore called **osmoconformers**. Other marine animals maintain extracellular fluid osmolarities much lower than seawater and are therefore called **osmoregulators**. All marine vertebrates except for sharks and rays are osmoregulators. These animals maintain their extracellular fluids at about 300 mosm/l, like that of humans.

There are limits to osmoconformity. Even animals that can osmoconform over a wide range of osmolarities must osmoregulate in extreme environments. No animal could survive if its extracellular fluid had the osmolarity of fresh water. There would be too few solutes, including nutrients and ions essential for cell functions, and water would flow into the cells by osmosis, causing them to swell and burst. Nor could animals survive with internal osmolarities as high as those that may be

52.1 Osmoconformity Has Limits Animals that experience an extreme range of salt concentrations in their environment can be osmoconformers over much of that range but must osmoregulate at the extremes. They regulate by actively transporting ions across their gill membranes—in either direction, depending on the challenge.

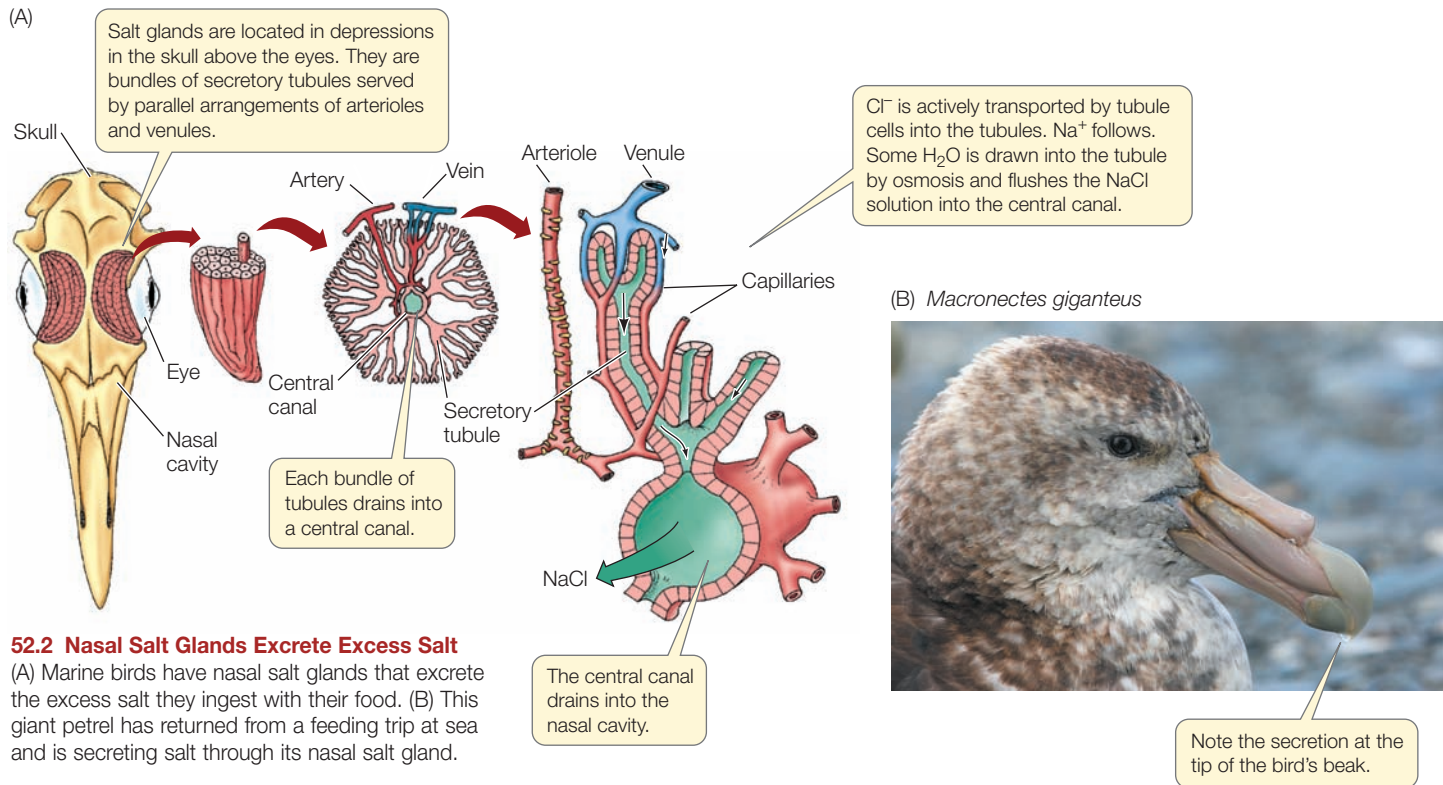

reached in an evaporating tidal pool. High solute concentrations cause proteins to denature.

The brine shrimp *Artemia* is both an osmoconformer and an osmoregulator; this animal can live in environments of almost any osmolarity (Figure 52.1). *Artemia* are found in huge numbers in the most salty environments known, such as Utah's Great Salt Lake and in coastal evaporation ponds where salt is concentrated for commercial purposes (see Figure 26.23) and can reach an osmolarity of 2,500 mosm/l. At these high environmental osmolarities, *Artemia* maintains its tissue fluid osmolarity considerably below that of the environment by actively transporting NaCl from its extracellular fluid out across its gill membranes to the environment. *Artemia* cannot survive in fresh water, but it can live in dilute seawater by reversing the direction of transport of NaCl across its gill membranes to maintain its extracellular fluid above that of the environment.

Animals can be ionic conformers or ionic regulators

Osmoconformers can also be ionic conformers, allowing the ionic composition, as well as the osmolarity, of their extracellular fluid to match that of the environment. Most osmoconformers, however, are ionic regulators to some degree; they employ active transport mechanisms to excrete some ions and to maintain other ions in their extracellular fluid at optimal concentrations.

Terrestrial animals obtain their salts from food and regulate the ionic composition of their extracellular fluids by conserving some ions and excreting others. For example, herbivores have to conserve Na⁺ because the plants they eat have low concen-

52.2 Nasal Salt Glands Excrete Excess Salt

(A) Marine birds have nasal salt glands that excrete the excess salt they ingest with their food. (B) This giant petrel has returned from a feeding trip at sea and is secreting salt through its nasal salt gland.

trations of Na^+ . By contrast, birds that feed on marine animals must excrete the excess of sodium they ingest with their food. Their *nasal salt glands* excrete a concentrated solution of NaCl via a duct that empties into the nasal cavity. Birds, such as penguins and gulls, that have nasal salt glands can be seen frequently sneezing or shaking their heads to get rid of the salty droplets excreted from their nasal salt glands (**Figure 52.2**).

52.1 RECAP

Excretory systems control water and salt balance and the excretion of nitrogenous waste products through three mechanisms: filtration of body fluids to form urine, active secretion of substances into the urine, and active reabsorption of substances from the urine.

- Describe the two mechanisms used to move water across membranes. **See p. 1093**
- What different salt and water balance problems might animals encounter in marine, freshwater, and terrestrial environments? What are some of the ways they meet those challenges? **See pp. 1093–1094 and Figures 52.1 and 52.2**

In addition to maintaining salt and water balance, animals must eliminate the waste products of metabolism from their extracellular fluids. The major problem is nitrogen. When nitrogen-containing molecules are broken down by metabolism, the end product can be toxic.

52.2 How Do Animals Excrete Nitrogen?

The end products of the metabolism of carbohydrates and fats are water and carbon dioxide, which are not difficult to eliminate. Proteins and nucleic acids, however, contain nitrogen, so their metabolism produces *nitrogenous wastes* in addition to water and carbon dioxide.

Animals excrete nitrogen in a number of forms

The most common nitrogenous waste is **ammonia** (NH_3). Because it is highly toxic, ammonia is either excreted continuously to prevent its accumulation or is detoxified by conversion into **urea** or **uric acid** (**Figure 52.3**).

AMMONIA Ammonia is highly soluble in water and diffuses rapidly, so its continuous excretion is relatively simple for many aquatic animals that continuously lose ammonia from their blood to the environment by diffusion across their gill membranes. Animals that excrete ammonia, such as aquatic invertebrates and bony fishes, are **ammonotelic**.

If ammonia builds up in the extracellular fluids, it becomes toxic at rather low levels and is a dangerous metabolite for terrestrial animals and for those aquatic animals that cannot continuously excrete ammonia. These animals must convert ammonia into urea or uric acid.

UREA **Ureotelic** animals, such as mammals, amphibians, and cartilaginous fishes (sharks and rays), excrete urea as their principal nitrogenous waste product. Urea is quite soluble in water,

52.3 Waste Products of Metabolism The metabolism of proteins and nucleic acids produces nitrogenous wastes. Many aquatic animals, including most fishes, excrete nitrogenous wastes as ammonia, which is highly diffusible and soluble in an aqueous environment. Most terrestrial animals and some aquatic animals excrete either urea or uric acid. Urea is more soluble in water and is the major nitrogenous excretory product for mammals, amphibians, and some fishes. Uric acid is not very soluble in water and is the major nitrogenous excretory product for reptiles, birds, insects, and some amphibians.

Species that live in different habitats at different developmental stages may use more than one mechanism of nitrogen excretion. The tadpoles of frogs and toads, for example, excrete ammonia across their gill membranes, but adult frogs and toads generally excrete urea. Some adult amphibians that live in arid habitats excrete uric acid.

but its excretion can result in a large loss of water that many animals can ill afford. As we will see later in this chapter, mammals have evolved excretory systems that conserve water by producing concentrated urea solutions. The sharks and rays are another story. These marine species keep their extracellular fluids almost isosmotic (same osmotic concentration) to the marine environment by retaining high concentrations of urea and another nitrogen-containing compound, trimethylamine oxide, in their body fluids.

URIC ACID Animals that conserve water by excreting nitrogenous wastes mostly as uric acid are **uricotelic**. Insects, reptiles (including birds), and some amphibians are uricotelic. Uric acid is not very soluble in water, so it forms a colloidal suspension in the urine and is excreted as a semisolid (for example, the whitish material in bird droppings). A uricotelic animal loses very little water as it disposes of its nitrogenous wastes.

Most species produce more than one nitrogenous waste

Humans are ureotelic, but we also excrete uric acid. The uric acid in human urine comes largely from the metabolism of nucleic acids and caffeine. If uric acid levels in the extracellular fluids rise too high, uric acid crystals can precipitate in joints and cause the age-old malady called gout. Because solubility goes down with temperature, uric acid crystals usually precipitate first in the extremities, especially the big toe. Pain in the big toe is a telltale symptom of gout.

Humans can also excrete ammonia, which is an important mechanism for regulating the pH of the extracellular fluids. As we will see later in this chapter, excreted ammonia buffers the urine and enables the secretion of more hydrogen ions.

52.2 RECAP

Ammonia is a common metabolic waste product of nitrogen-containing molecules. Most aquatic animals excrete ammonia by diffusion into the water. Terrestrial animals and some aquatic animals detoxify it by conversion to urea or uric acid.

- Why might you expect a species from an arid habitat to use uric acid as its primary nitrogenous waste product? **See p. 1095 and Figure 52.3**

Animals exhibit a variety of adaptations for dealing with the challenges of salt and water balance in different environments. All of these adaptations, however, are based on two basic mechanisms—namely, filtration and tubular processing of the filtrate to conserve some solutes and excrete others.

52.3 How Do Invertebrate Excretory Systems Work?

Freshwater and terrestrial invertebrates have a wide variety of adaptations for maintaining salt and water balance and excreting nitrogen. In this section, we will explore three examples of invertebrate excretory systems: *protonephridia*, *metanephridia*, and *Malpighian tubules*. Each of these systems produces an extract of interstitial fluid lacking in large molecules. They then change the solute composition (ions and small molecules) of that fluid to form an excretory product.

The protonephridia of flatworms excrete water and conserve salts

Many flatworms, such as *Planaria*, live in fresh water. These animals excrete water through an elaborate network of tubules

52.4 Protonephridia in Flatworms The protonephridia of the flatworm *Planaria* consist of tubules ending in flame cells. In the region of the flame cells, body fluid is filtered between the tubule cells. The composition of the filtrate is modified as it flows down the tubule.

running throughout their bodies. The tubules end in *flame cells*, so called because each cell has a tuft of cilia projecting into the tubule (Figure 52.4). The beating of the cilia gives the appearance of a flickering flame. A flame cell and a tubule together form a **protonephridium** (plural protonephridia; Greek *proto*, “before,” and *nephros*, “kidney”).

Extracellular fluid enters the tubules by filtration. The beating of the cilia causes a slight negative pressure in the tubule, and movements of the animal create positive pressure in the extracellular fluid. This pressure difference causes extracellular fluid to be filtered through tiny spaces between tubule cells. The filtrate flows toward the animal’s excretory pore, and along the way the cells of the tubules modify the composition of the fluid by reabsorption and secretion of specific ions and molecules. Because more ions are reabsorbed than are secreted, the urine that leaves the flatworm’s body is less concentrated than the extracellular fluid. Thus, the protonephridium conserves ions and excretes water and wastes.

The metanephridia of annelids process coelomic fluid

Filtration of body fluids and modification of urine by tubules are highly developed processes in annelid worms such as the earthworm. Annelids are segmented, and in each segment they have a fluid-filled body cavity called a *coelom* (see Figure 32.12). Annelids have a closed circulatory system through which blood is pumped under pressure. The pressure causes the blood to be filtered across the thin,

permeable capillary walls into the coelom. Some waste products, such as ammonia, diffuse directly from the tissues into the coelom. Where does this coelomic fluid go?

Each segment of the earthworm contains a pair of **metanephridia** (singular metanephridium; Greek *meta*, “akin to,” and *nephros*, “kidney”). Each metanephridium begins as a ciliated, funnel-like opening called a *nephrostome*. The nephrostome resides in one segment and continues as a tubule in the next segment. The tubule ends in a pore, called a *nephridiopore*, that opens to the outside of the animal (Figure 52.5). Coelomic fluid is swept into the metanephridia through the ciliated nephrostomes. As the fluid passes through the tubules, their cells actively reabsorb certain molecules from it and actively secrete other molecules into it. What leaves the animal through the nephridiopores is a dilute urine containing nitrogenous wastes and other solutes.

52.5 Metanephridia in Earthworms The metanephridia of annelids are arranged segmentally. The cross section at the left end shows a pair of metanephridia. Three longitudinal sections (right) show only one metanephridium of the two in each segment. Coelomic fluid enters the nephrostome and flows through tubules leading to the nephridiopore. A close association of the tubules and blood capillaries facilitates the active exchange of substances between the blood and the tubular fluid.

52.6 Malpighian Tubules in Insects The blind, thin-walled Malpighian tubules are attached to the junction of the insect's midgut and hindgut and project into the spaces containing extracellular fluid. This system makes it possible to excrete wastes with very little loss of water.

The Malpighian tubules of insects depend on active transport

Insects can excrete nitrogenous wastes with very little loss of water and can therefore live in the driest habitats on Earth. The insect excretory system consists of **Malpighian tubules**. An individual insect has from 2 to more than 100 of these blind-ended tubules that open into the gut between the midgut and hindgut (**Figure 52.6**).

Insects have an open circulatory system and therefore cannot use a pressure difference to filter extracellular fluids into the Malpighian tubules. Instead, the cells of the tubules actively transport uric acid, potassium ions, and sodium ions from the extracellular fluid into the tubules. The high concentration of solutes in the tubules causes water to follow osmotically, which flushes the tubule contents toward the gut.

The epithelial cells of the hindgut and rectum actively transport sodium and potassium ions from the gut contents back into the extracellular fluid. This local transport of salts creates an osmotic gradient that pulls water out of the rectal contents. As its concentration increases, the uric acid forms a colloidal suspension, freeing even more water to be reabsorbed. Remaining in the rectum is the uric acid mixed with other wastes; this semisolid matter is what the insect excretes. The Malpighian tubule system is a highly effective mechanism for excreting nitrogenous wastes and some salts without giving up much water.

52.3 RECAP

Protonephridia and metanephridia work by creating a filtrate of the body fluids that is modified by the secretion and reabsorption of specific substances before being excreted. Insect Malpighian tubules actively secrete uric acid and other solutes into closed tubules.

- Describe how an earthworm filters its blood and produces urine. **See p. 1096 and Figure 52.5**
- How do Malpighian tubules function, and how does this system make it possible for some insect species to survive in the desert? **See p. 1097 and Figure 52.6**

Having described how several invertebrate groups handle nitrogen excretion, we will next consider the nephron—the basic unit of the vertebrate excretory system—and how it evolved to be able to respond to a variety of salt and water balance challenges and maintain a relatively constant internal environment.

52.4 How Do Vertebrates Maintain Salt and Water Balance?

The main excretory organ of vertebrates is the **kidney**, and the functional unit of the kidney is the **nephron**, which has a blood vessel component and a tubule component. The vascular component begins with a knot of capillaries that are highly permeable and filter the blood into the tubule component. The blood vessels also carry substances to the tubules for secretion and carry away substances that the tubule cells reabsorb. Nephrons can filter large volumes of blood and achieve bulk reabsorption of salts and other valuable molecules such as glucose, making the vertebrate kidney well adapted for the excretion of excess water.

If the ancestors of vertebrates evolved in fresh water, as paleontologists propose, the excretory systems of vertebrates would have evolved to excrete excess water. How then have vertebrates adapted to environments where water must be conserved and salts excreted? The answer to this question differs among vertebrate groups. Even among the marine fishes, the excretory adaptations of the bony fishes are different from those of the cartilaginous fishes. Reptiles, birds, and mammals have excretory systems that conserve water. Reptiles and birds achieve this mainly by being uricotelic and producing a semi-solid excretory product that contains little water. Mammals in contrast are ammonotelic, excrete a liquid waste product, but have evolved the ability to produce a highly concentrated urine.

Marine fishes must conserve water

Marine bony fishes osmoregulate their extracellular fluids to maintain them at one-third to one-half the osmolarity of seawater. Their only source of water is the sea around them, so they must conserve water and excrete excess solutes. Marine bony fishes cannot produce urine that is more concentrated than their extracellular fluids, so they minimize water loss by producing very little urine. In contrast, freshwater fishes produce lots of dilute urine.

If marine bony fishes cannot excrete excess solutes in their urine, how do they deal with the large salt loads they ingest with food? Marine bony fishes do not absorb from their guts some of the ions they take in, especially divalent ions such as Mg^{2+} or SO_4^{2-} . NaCl, the major salt ingested, is actively excreted across the gill membranes. As we mentioned earlier, bony fishes can lose their nitrogenous waste, ammonia, by diffusion across their gill membranes.

Cartilaginous fishes (sharks and rays) are osmoconformers but not ionic conformers. They raise the osmolarity of their body fluids in a unique way. Unlike bony fishes, they convert nitrogenous wastes to urea and trimethylamine oxide, and they retain large amounts of these compounds in their body fluids. As a result, their body fluids have an osmolarity close to that of seawater, so they do not lose body water to the environment by osmosis, and may actually gain water. These species have adapted to a concentration of urea in the body fluids that would be toxic to other vertebrates.

Sharks and rays still have the problem of excreting the large amounts of salts they take in with their food. They solve this problem by having a gland in the rectum that actively secretes NaCl by a mechanism similar to that of the nasal salt glands of seabirds.

Terrestrial amphibians and reptiles must avoid desiccation

Most amphibians live in or near fresh water, and they stay in humid habitats when they do venture from the water. Like freshwater fishes, most amphibians produce large amounts of dilute urine and conserve salts. Some amphibians, however, have adapted to habitats that require water conservation.

Amphibians living in dry terrestrial environments have reduced the permeability of their skin to water. Some secrete a

waxy substance over the skin to waterproof it. Several species of frogs that live in arid regions of Australia burrow deep into the ground and remain there during long dry periods. They enter **estivation**, a state of very low metabolic activity and therefore low water turnover. When it rains, the frogs come out of estivation, feed, and reproduce. Their most interesting adaptation is an enormous urinary bladder. Before entering estivation, they fill the bladder with dilute urine, which can amount to one-third of their body weight. This dilute urine serves as a water reservoir that is gradually reabsorbed into the blood during the long period of estivation.

Reptiles occupy habitats ranging from aquatic to extremely hot and dry. In fact, snakes, lizards, and birds are among the most prominent members of many desert faunas. Three major adaptations have freed reptiles from the close association with water that is necessary for most amphibians (see Section 33.4). First, reptiles are *amniotes* that do not need fresh water to reproduce because they employ internal fertilization and lay eggs with shells that retard evaporative water loss. Second, they have a dry, epidermis (skin) that retards evaporative water loss. Third, they excrete nitrogenous wastes as uric acid semisolids, losing little water in the process.

Mammals can produce highly concentrated urine

Mammals occupy diverse habitats, many of which present special excretory system challenges. The most challenging environments are those in which water is severely limited. Mammals have a variety of adaptations to conserve water, but chief among them is the ability to produce a urine that is more concentrated than their extracellular fluids. They are able to concentrate their urine because of adaptations of their kidneys that we will explore in detail in Section 52.5. To understand how these adaptations work, however, we must first describe the structure and function of the vertebrate nephron.

The nephron is the functional unit of the vertebrate kidney

Urine formation in vertebrate nephrons involves three main processes (**Figure 52.7**):

- **Filtration.** Each nephron has a dense ball of capillaries called a **glomerulus** (plural glomeruli). The glomerulus is highly permeable to water, ions, and small molecules but impermeable to large molecules. Blood pressure drives the movement of water and small molecular weight solutes out of the glomerular capillaries.
- **Tubular reabsorption.** The filtrate from the glomerulus flows into the **renal tubule**. Cells in the renal tubule modify the filtrate by reabsorbing specific ions, nutrients, and water, returning these to the blood, and leaving behind and concentrating excess ions and waste products such as urea.
- **Tubular secretion.** The filtrate in the renal tubule is further modified by tubule cells transporting substances into the tubular contents. These are substances that the body needs to excrete.

Blood enters the glomerular capillaries via an **afferent arteriole** and leaves the glomerulus in an **efferent arteriole**. This short vessel is called an arteriole because it feeds another capillary bed called the **peritubular capillaries** that intimately surround the renal tubules (**Figure 52.8A**). Peritubular capillaries deliver substances to the renal tubule cells that they will secrete into the urine and carry away substances these cells absorb from the urine.

52.7 The Vertebrate Nephron The vertebrate nephron consists of a renal tubule closely associated with two capillary beds, the glomerulus and the peritubular capillaries.

yourBioPortal.com

GO TO Web Activity 52.2 • The Vertebrate Nephron

Blood is filtered into Bowman's capsule

The renal tubule begins with **Bowman's capsule** (see **Figure 52.7**), which encloses the glomerulus. The glomerulus appears to be pushed into Bowman's capsule much like a fist pushed into an inflated balloon. The cells of the capsule that are in direct contact with the glomerular capillaries are called **podocytes** (**Figure 52.8B**). These highly specialized cells have numerous armlike extensions, each with hundreds of fine, fingerlike processes. The podocytes wrap around the capillaries so that their processes interdigitate and intimately cover the capillaries.

The glomerulus filters the blood to produce a fluid (the renal filtrate) that lacks cells and large molecules. The walls of the capillaries, the basal lamina of the capillary endothelium, and the podocytes of Bowman's capsule all participate in filtration. *Fenestrations* in the walls of the capillaries (see **Section 50.4**) allow water and many solute molecules, but not red blood cells, to pass through. The meshwork of the basal lamina and the spaces between the processes of the podocytes are even finer and prevent large molecules from leaving the capillaries (**Figure 52.8C**). The arterial pressure of the blood entering the permeable capillaries causes the filtration of water and small molecules in the glomerulus. The glomerular filtration rate is high because blood

52.8 A Tour of the Nephron Scanning electron micrographs illustrate the anatomical basis for blood filtration by the kidneys. (A) In a preparation showing only the blood vessels (tubular tissue has been digested away), the glomeruli appear as balls of capillaries served by arterioles. (B) Higher magnification of a glomerulus with the tubule cells intact shows the podocytes that wrap around the glomerular capillaries. (C) This cross section of an intact glomerulus shows the tubule cells that form Bowman's capsule.

pressure in the glomerular capillaries is unusually high, and because the capillaries of the glomerulus, along with their covering of podocytes, are more permeable to water than other capillary beds in the body.

The renal tubules convert glomerular filtrate to urine

The composition of the filtrate that enters the renal tubule is similar to that of the blood plasma, with the exception of high-molecular-weight solutes such as proteins. Reabsorption and secretion cause the composition of this fluid to change as it passes down the renal tubule. Cells of the tubule actively reabsorb certain molecules from the tubule fluid (which are returned to the blood flowing through the peritubular capillaries). For example, glucose and amino acids are reabsorbed. Most NaCl is reabsorbed. Other substances in the blood of the peritubular capillaries are actively secreted into the tubule fluid. An example is paraminohippuric acid (PAH), which is produced in the liver from benzoic acid, a common food preservative. Because of the actions of the renal tubules, the excreted urine is very different from the original filtrate.

52.4 RECAP

The kidney is the major excretory organ of vertebrates. Its functional unit is the nephron, which includes a glomerulus that filters blood and a renal tubule that secretes and reabsorbs solutes, modifying the filtrate to produce urine. The nephron is a mechanism for excreting excess water while conserving valuable solutes.

- Explain the difference in the osmoregulatory adaptations of marine bony and cartilaginous fishes. **See p. 1098**
- What are the functional relationships between the glomerular and peritubular capillaries? **See p. 1099 and Figure 52.7**
- Describe how blood is filtered by the glomerulus. **See pp. 1099–1100**
- How is the composition of the urine made different from the composition of the blood? **See p. 1100**

The adaptations that enable the mammalian kidney to produce urine more concentrated than extracellular fluids were important steps in vertebrate evolution, and they were largely achieved through changes in the structure and regional functions of the renal tubules.

52.5 How Does the Mammalian Kidney Produce Concentrated Urine?

Mammals have high body temperatures and high metabolic rates, and therefore have the potential for a high rate of water loss. Having an excretory system that minimizes water loss made it possible for these highly active species to occupy arid habitats.

Kidneys produce urine, and the bladder stores it

Mammalian excretory systems are similar, so we will use that of humans as our example. Humans have two kidneys at the back of the upper region of the abdominal cavity (**Figure 52.9A**). Each kidney filters blood, processes the filtrate into urine, and releases that urine into a duct called the **ureter**. The ureter of each kidney leads to the **urinary bladder**, where the urine is stored until it is excreted through the **urethra**, a short tube that opens to the outside of the body.

Two sphincter muscles surrounding the base of the urethra control urination. One of these sphincters is a smooth muscle and is controlled by the autonomic nervous system. As the bladder fills, stretch receptors in the walls of the bladder trigger a spinal reflex that relaxes this sphincter. This reflex is the only control of urination in infants, hence their frequent “accidents.” The other sphincter is a skeletal muscle and is controlled by the voluntary nervous system. When the bladder is *very* full, only deliberate conscious effort prevents urination. Infant toilet training involves learning to control this sphincter.

yourBioPortal.com

GO TO Animated Tutorial 52.1 • The Mammalian Kidney

Nephrons have a regular arrangement in the kidney

The kidney is shaped like a kidney bean; when sliced along its long axis, its key anatomical features are revealed (**Figure 52.9B**). The ureter and the **renal artery** and **renal vein** enter the kidney on its concave (punched-in) side. The ureter extends into the kidney in several branches, the ends of which envelop kidney tissues called **renal pyramids**. The renal pyramids make up the internal core, or **medulla**, of the kidney. The medulla is covered by an outer layer, or **cortex**, that has a granular appearance. Between the cortex and the medulla, the renal artery divides into the many arterioles that serve the nephrons. In this same region, the renal vein collects blood from the many venules that drain the peritubular capillaries.

The organization of the nephrons within the kidney is very regular. All of the glomeruli with their Bowman’s capsules are located in the cortex. The initial segment of a renal tubule is called the **proximal convoluted tubule**—“proximal” because it is closest to the glomerulus, and “convoluted” because it is twisted (**Figure 52.9C**). All of the proximal convoluted tubules are also located in the cortex.

At the point at which the renal tubule descends into the medulla, it straightens and descends directly down into the medulla. In the medulla the tubule makes a hairpin turn and ascends back to the cortex, forming what is called the **loop of Henle**. Some nephrons have longer loops of Henle than others. Some 20 to 30 percent of human nephrons that have glomeruli deep in the cortex (i.e., near the border with the medulla) have long loops of Henle that go deep into the medulla. Nephrons that have glomeruli farther up in the cortex generally have short loops of Henle that descend only a short distance into the medulla. As we will see, the long loops are the critical adaptation of the mammalian nephron that enables the kidney to concentrate the urine.

52.9 The Human Excretory System (A) The human kidneys lie against the back wall of the abdominal cavity, in the region of the middle back. (B) A highly organized internal structure is the basis for kidney function. Certain parts of the nephrons are in the organ's outer region, called the cortex; other parts are in the internal region, called the medulla. (C) The glomeruli and the proximal and distal convoluted tubules are located in the cortex of the kidney. The loops of Henle run in parallel as straight sections down into the renal medulla and back up to the cortex. Collecting ducts run from the cortex to the inner surface of the medulla, where they open into the ureter. The vasa recta are peritubular capillaries that parallel the loops of Henle.

yourBioPortal.com

GO TO Web Activity 52.3 • The Human Excretory System

The *ascending limb* of the loop of Henle becomes the **distal convoluted tubule** when it reaches the cortex—"distal" because it is farther from the glomerulus. The distal convoluted tubules of many nephrons join a common **collecting duct** in the cortex. The collecting ducts descend back down through the renal pyramid, parallel to and past the tips of the loops of Henle, and empty into the funnel-shaped *pelvis*. Divisions of the pelvis that surround each renal pyramid join together to leave the kidney as the ureter (see Figure 52.9B).

The organization of the blood vessels of the kidney closely parallels the organization of the nephrons (see Figure 52.9C).

Smaller arteries branch from the renal artery and radiate into the cortex, forming the afferent arterioles that carry blood to each glomerulus. Each glomerulus is drained by an efferent arteriole that gives rise to the peritubular capillaries, most of which surround the cortical portions of the tubules. As we have seen, the intimate association between the glomerular and peritubular capillaries permits exchanges between the blood and the specialized regions of the nephron tubule.

Some of the peritubular capillaries run into the medulla in parallel with the loops of Henle and the collecting ducts, forming a vascular network called the **vasa recta**. All of the peritubular capillaries from a nephron join back together into a venule that joins with venules from other nephrons and eventually leads to the renal vein. As we will see, the concentrating ability of the mammalian kidney depends on water reabsorption in the renal medulla, and the vasa recta are the avenue by which that water gets out of the renal medulla and into the circulation.

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule

Most of the water and solutes filtered by the glomerulus are reabsorbed and do not appear in the urine. We can reach this con-

clusion by comparing the rate of filtration by the glomeruli with the rate of urine production. The kidneys receive about 1 liter of blood per minute, or about 1,500 liters of blood per day. How much of this huge volume is filtered out of the glomeruli? The answer is about 12 percent. This is still a large volume—180 liters per day! We normally urinate 2 to 3 liters per day, so about 98 percent of the fluid volume that is filtered out of the glomerulus is returned to the blood. Where and how is this enormous fluid volume reabsorbed?

The proximal convoluted tubule (PCT) is responsible for most of the reabsorption of water and solutes from the glomerular filtrate. The cells of this section of the renal tubule have many microvilli that increase their apical (facing into the tubule) surface area for reabsorption, and they have many mitochondria—an indication that they are metabolically active. PCT cells actively transport Na^+ (with Cl^- following) and other solutes, such as glucose and amino acids, out of the tubule fluid.

Almost all glucose and amino acid molecules that are filtered from the blood are actively reabsorbed by PCT cells and transported into the extracellular fluid. The active transport of solutes from the proximal tubule into the interstitial fluid causes water to follow osmotically. The water and solutes moved into the interstitial fluid are taken up by the peritubular capillaries and returned to the venous blood. These processes accomplish the reabsorption of more than 75 percent of the fluid that initially enters the nephron.

Despite the bulk reabsorption of water and solutes by the PCT, the overall osmolarity of the fluid flowing through the PCT does not change. Thus, the process that is occurring in the PCT is called *isosmotic reabsorption*. The fluid that enters the loop of Henle has the same osmolarity as the blood plasma, although its composition is different. How then does the kidney produce urine that is more concentrated than the blood plasma?

The loop of Henle creates a concentration gradient in the renal medulla

Humans can produce urine that is four times more concentrated than their blood plasma. The vampire bat we encountered at the beginning of this chapter can produce urine that is twenty times more concentrated than its blood plasma. The concentrating ability of the mammalian kidney arises from a **countercurrent multiplier** mechanism made possible by the anatomical arrangement of the loops of Henle. The term “countercurrent” refers to the opposing directions in which the tubule fluid in the descending and ascending limbs flows. The term “multiplier” refers to the ability of this system to create a solute concentration gradient in the renal medulla.

The loops of Henle do not themselves produce concentrated urine; rather, they increase the osmolarity of the extracellular fluid in the medulla in a graduated way. In humans, for example, the extracellular fluid may be 300 mosm/l (the concentration of blood plasma) at the top of the medulla bordering the cortex, and increase to about 1,200 mosm/l near the hairpin turn of the loop of Henle (see Figure 52.10). How do the loops produce this effect?

The cells that make up the different segments of the loop of Henle differ anatomically and functionally. Cells of the descending limb and the initial cells of the ascending limb are thin, with no microvilli and few mitochondria. They are not specialized for transport. Partway up the ascending limb, the cells become specialized for active transport. These cells are thick and have many mitochondria. Accordingly, the segments of the loop of Henle are named the *thin descending limb*, the *thin ascending limb*, and the *thick ascending limb* (Figure 52.10).

The countercurrent multiplier mechanism may be more easily understood by first considering events occurring in the thick ascending limb (Figure 52.10, note 1). The cells of the thick ascending limb reabsorb Na^+ and Cl^- from the tubule fluid and move it into the interstitial fluid. (In the following discussion, we will distinguish between the two components of extracellular fluid—the blood plasma and the interstitial fluid.) The thick ascending limb is not permeable to water, so the reabsorption of Na^+ and Cl^- from the tubular fluid raises the concentration of those solutes in the surrounding interstitial fluid and decreases the concentration of the tubular fluid entering the distal convoluted tubule.

The thin descending limb, in contrast, is highly permeable to water but not very permeable to Na^+ and Cl^- . Since the local interstitial fluid has been made more concentrated by the Na^+ and Cl^- reabsorbed from the neighboring thick ascending limb, water is withdrawn osmotically from the tubule fluid in the descending limb. Therefore, the fluid in the descending limb becomes more concentrated as it flows toward the hairpin turn at the bottom of the renal medulla (Figure 52.10, note 2).

The thin ascending limb, like the thick ascending limb, is not permeable to water. It is, however, permeable to Na^+ and Cl^- . As the concentrated tubule fluid flows up the thin ascending limb, it is more concentrated than the surrounding interstitial fluid, so Na^+ and Cl^- diffuse out. When the tubule fluid reaches the thick ascending limb, active transport continues to move Na^+ and Cl^- from the tubule fluid to the interstitial fluid.

As a result of the processes described above, the tubule fluid reaching the distal convoluted tubule is less concentrated than the blood plasma (Figure 52.10, note 3), and the solutes that have been left behind in the renal medulla have created a concentration gradient in the interstitial fluid of the medulla (indicated by the background color gradient in Figure 52.10).

You may wonder why the blood flow through the medulla does not wash out the concentration gradient established by the loops of Henle. The parallel arrangement of the descending and ascending peritubular capillaries—the vasa recta—in the medulla helps preserve the concentration gradient in the medulla. These capillaries are permeable to both salt and water. Therefore, as blood flows down the descending limb of the vasa recta into the increasingly concentrated interstitial fluid of the medulla, it loses water and gains solutes. As blood flows up from the bottom of the medulla in the ascending limb of the vasa recta, the opposite happens (water is gained and solutes are lost) because now the blood is more concentrated than the surrounding interstitial fluid (Figure 52.10, notes 4–6). The dynamics of this countercurrent exchange of salts and water be-

52.10 Concentrating the Urine A countercurrent multiplier mechanism enables the mammalian kidney to produce urine that is far more concentrated than the blood plasma. The composition—but not the concentration—of the filtrate is changed by the proximal convoluted tubule, which reabsorbs valuable molecules (including NaCl). Bulk reabsorption of water follows osmotically. The urine concentration process begins in the thick ascending limb of Henle, which reabsorbs NaCl but is impermeable to H₂O. Some of the reabsorbed NaCl enters the descending limb and is thereby trapped in the renal medulla, creating a concentration gradient in the interstitial fluid. As urine in the collecting duct passes through this concentration gradient, it can lose water osmotically and become highly concentrated.

tween the blood in the vasa recta and the interstitial fluids result in little net change in the composition of the interstitial fluid in the medulla.

Water permeability of kidney tubules depends on water channels

We have noted that some tubule regions, such as the PCT, are highly permeable to water while others, such as the thick as-

cending limb of the loop of Henle, are impermeable to water. How do differences in water permeability in different regions of the nephron arise? Regions of the nephron that are highly permeable to water have greater numbers of *aquaporins*, a class of membrane proteins that form water channels (see Section 6.3). Aquaporins are abundant in kidney PCT cells and in descending limbs of the loops of Henle, but not in the ascending limbs of the loop of Henle. The discovery of aquaporins resulted in Peter Agre of Johns Hopkins University receiving the Nobel Prize in Chemistry in 2003.

As an interesting evolutionary note, aquaporins are also important in maintaining water balance in amphibians. When not in an aqueous environment, many amphibians can gain water from a moist substrate because they have aquaporins in the epithelial cells of their belly skin. Thus, water can cross their skin into the interstitial fluid by osmosis.

The distal convoluted tubule fine-tunes the composition of the urine

The first portion of the distal convoluted tubule is similar to the thick ascending limb of the loop of Henle. Na^+ and Cl^- are transported out of the tubule fluid, and water cannot follow. As a result, the tubule fluid becomes even more dilute. The later sections of the distal convoluted tubule, however, can be permeable to water, and water can be osmotically drawn from the tubule into the interstitial fluid. As the tubule fluid flows from the distal tubule to the collecting duct, it can be below or equal to the osmolarity of the blood plasma.

An important function of the distal tubule is the fine-tuning of the ionic composition of the urine. Even though bulk reabsorption of substances such as calcium, phosphate, bicarbonate, and potassium occurs in the proximal convoluted tubule, changes in the concentrations of these substances occur in the distal convoluted tubule. In the case of potassium, for example, if a person is potassium depleted, this ion is reabsorbed in the distal convoluted tubule, but if a person has an abundance of potassium, this ion is secreted in the distal convoluted tubule. As we will see below, this exchange of K^+ is controlled by the hormone *aldosterone*. Another example is reabsorption of Ca^{2+} in the distal convoluted tubule, which is controlled by the actions of vitamin D. The fine-tuning of urine composition continues in the collecting duct. As you can imagine, the list of ion transporters in the distal convoluted tubule is large.

Urine is concentrated in the collecting duct

The tubule fluid entering the collecting duct is at about the same solute *concentration* as the blood plasma, but its solute *composition* is considerably different from that of the plasma. The major solute in the tubular fluid is now urea, since salts were reabsorbed earlier in the nephron. As the tubule fluid flows down the collecting duct, it loses water osmotically to the interstitial fluid, and that water returns to the circulatory system via the vasa recta (see Figure 52.10).

The concentration gradient established in the renal medulla by the countercurrent multiplier actions of the loops of Henle creates the osmotic potential that withdraws water from the collecting ducts. The collecting ducts begin in the renal cortex and run through the renal medulla before emptying into the ureter at the tips of the renal pyramids. During this journey, the solute concentration of the surrounding interstitial fluid increases, and more and more water can be absorbed from the urine in the collecting duct. By the time it reaches the ureter, the urine can become greatly concentrated, with urea as a major solute.

As water is withdrawn from the collecting duct, some urea also leaks out into the medullary interstitial fluid, adding to its osmotic potential. This urea diffuses back into the loop of Henle and is returned to the collecting duct. The recycling of urea in the renal medulla contributes significantly to the concentration gradient and therefore the ability of the kidney to concentrate the urine in the collecting duct.

Overall, the ability of a mammal to concentrate its urine is determined by the maximum concentration gradient it can es-

52.11 The Ability to Concentrate The ability of the mammalian kidney to concentrate urine depends on the lengths of its loops of Henle relative to the overall size of the kidney. The kidney of a desert gerbil has a single renal pyramid with loops of Henle so long that the pyramid extends far into the ureter (ureter not shown).

tablish in its renal medulla. An important adaptation for increasing the concentration gradient is to increase the lengths of the loops of Henle relative to overall kidney size. The small desert gerbil, for example, has such extremely long loops of Henle that its renal pyramid (each of its kidneys has only one, in contrast to ours) extends far out of the concave surface of the kidney and into the ureter (**Figure 52.11**). These animals are so effective in conserving water that they can survive just on the water released by the metabolism of their food.

The kidneys help regulate acid–base balance

Besides regulating salt and water balance and excreting nitrogenous wastes, the kidneys have another important role: they regulate the hydrogen ion concentration (the pH) of the extracellular fluids. pH is a critical variable because it influences the structure and function of proteins.

One way to minimize pH changes in a chemical solution is to add a *buffer*—a substance that can either absorb or release hydrogen ions (see Section 2.4). The major buffers in the blood are bicarbonate ions (HCO_3^- ; see Figure 49.14) that are formed from the dissociation of carbonic acid, which in turn is formed by the hydration of CO_2 according to the following equilibrium reaction:

From this equation, you can see that if excess hydrogen ions are added to this reaction mixture, the reaction will move to the left and absorb the excess H^+ . If hydrogen ions are removed from the reaction mixture, however, the reaction will move to the right and supply more H^+ .

The HCO_3^- buffer system is important for controlling the pH of the blood, and therefore of the interstitial fluids as well, because the reaction can be pushed to the right and pulled to the left physiologically. The lungs control the levels of CO_2 in the

blood, thus altering the acid portion of the reaction. CO_2 is considered the acid portion of the reaction because if you add additional CO_2 , the reaction shifts to the right, producing more H^+ ions. The kidneys control the base portion of the reaction by removing H^+ from the blood and returning HCO_3^- to the blood. How are H^+ ions removed from the blood?

One mechanism for H^+ secretion and HCO_3^- reabsorption involves ammonia (NH_3) and ammonium ion (NH_4^+). The metabolism of glutamine in tubule cells produces NH_3 and HCO_3^- . The HCO_3^- is reabsorbed into the interstitial fluid. The NH_3 is transported into the tubule fluid by means of an NH_3 transporter that has been characterized only recently in an effort to identify novel proteins coming from the sequencing of the human and other genomes (Figure 52.12).

Another mechanism for H^+ secretion and HCO_3^- reabsorption is shown in Figure 52.13. The H^+ is transported into the tubule fluid in exchange for Na^+ . The H^+ combines with HCO_3^- that has been filtered in the glomerulus, producing H_2CO_3 that

disassociates into H_2O and CO_2 . The CO_2 diffuses into the tubule cell where in the presence of the enzyme carbonic anhydrase it produces HCO_3^- that is transported into the interstitial fluid and thence to the blood.

Kidney failure is treated with dialysis

Loss of kidney function, or *renal failure*, results in the retention of salts and water (hence high blood pressure), retention of urea (uremic poisoning), and a decreasing pH (acidosis). A person who suffers complete renal failure will die within 2 weeks if not treated. A drastic but highly successful treatment is kidney transplant, but it is usually necessary to sustain a patient for considerable time while waiting for a kidney to become available. Therefore, artificial kidneys, or renal dialysis machines, are essential modes of treatment.

In a dialysis machine, the patient's blood flows through many small channels made of semipermeable membranes

INVESTIGATING LIFE

52.12 An Ammonium Transporter in the Renal Tubules?

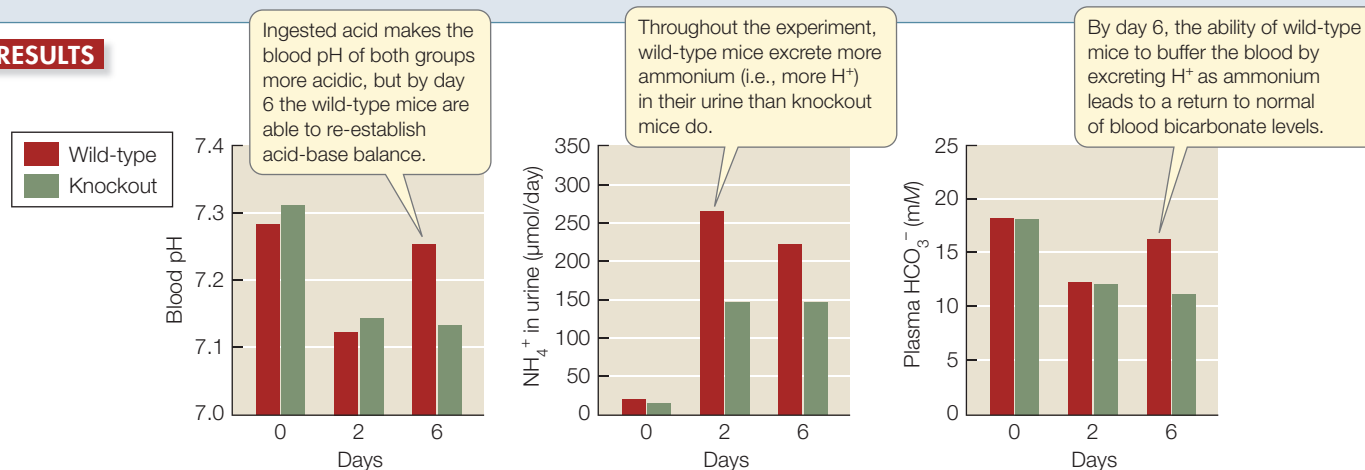

An important way the kidney excretes hydrogen ions and buffers the blood is to secrete ammonia (NH_3) into the renal tubules. It was thought that ammonia simply diffused into the tubules until the function of *Rhcg*, a protein in the Rh blood antigen family, was discovered. This experiment demonstrated that loss of the *Rhcg* gene in mice impairs their ability to buffer their blood pH by excreting excess H^+ (in the form of ammonium).

HYPOTHESIS The protein *Rhcg* is an ammonia transporter and is critical for the kidney's role in acid-base balance.

METHOD

1. Create a line of mice in which the gene for the protein *Rhcg* is knocked out (see Section 18.4).
2. Measure starting blood pH, plasma bicarbonate (HCO_3^-) levels, and urine ammonium (NH_4^+) levels in experimental and control (wild-type) mice.
3. For 6 days, administer drinking water containing NH_4Cl (ammonium chloride, a mild acid) to control mice and to *Rhcg* knockout mice.
4. Measure the three variables (see item 2 above) at days 2 and 6.

RESULTS

CONCLUSION Lack of functional *Rhcg* protein impairs a mouse's ability to secrete ammonium ions in its urine, thus limiting the capacity to regulate acid-base balance. This protein is probably an ammonia transporter in the renal tubules.

52.13 The Kidney Excretes Acids and Conserves Bases

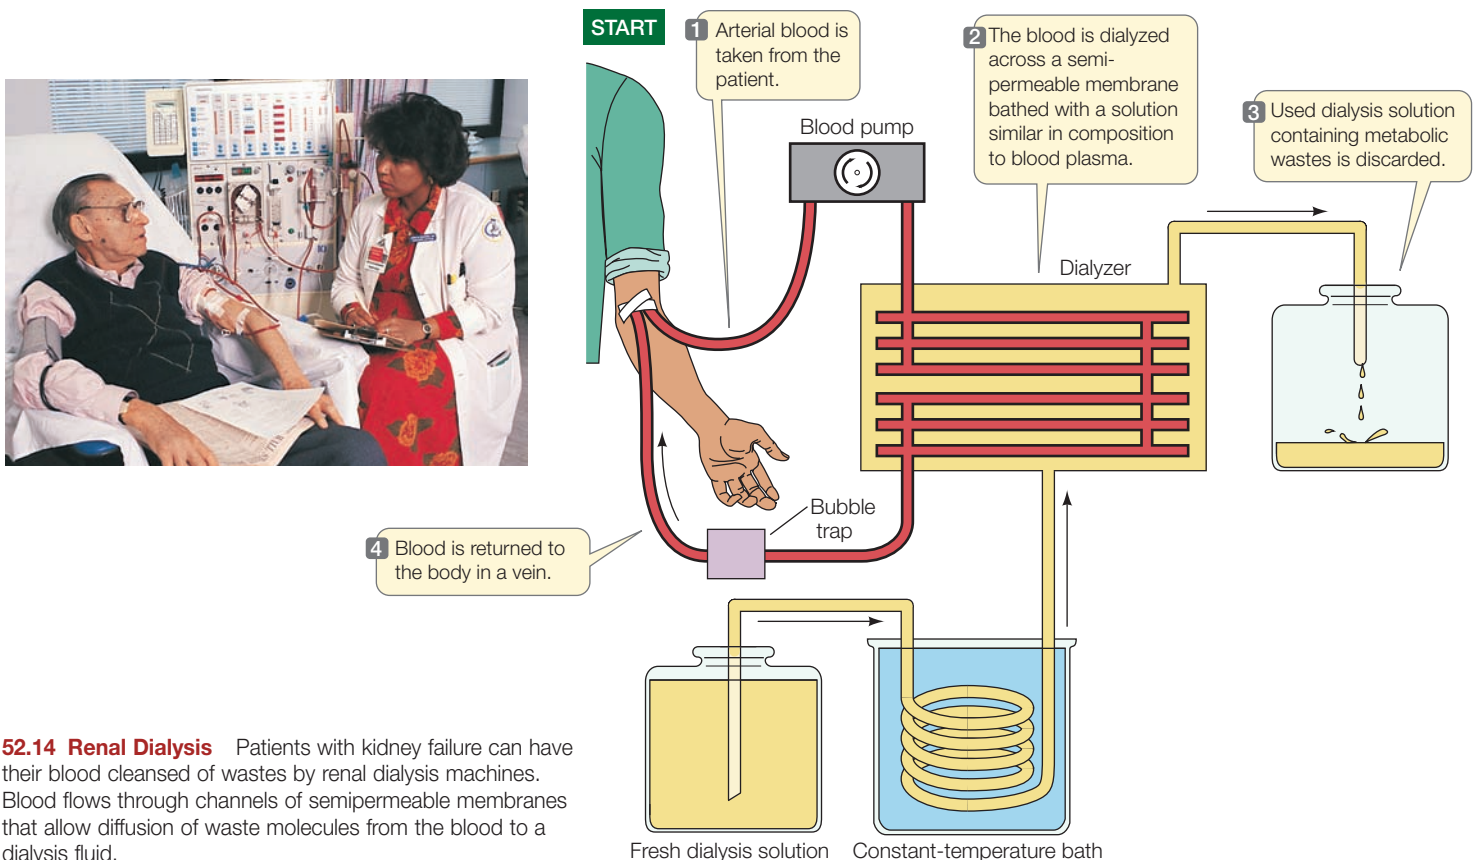

Bicarbonate ions are filtered out of the blood at the glomerulus, and renal tubule cells secrete hydrogen ions into the tubule fluid. In the renal tubule, the filtered bicarbonate buffers the secreted hydrogen ions and keeps the urine from becoming too acidic. The CO_2 formed by the reaction of bicarbonate and hydrogen ions is converted back to bicarbonate by the renal tubule cells and transported back into the interstitial fluid.

(Figure 52.14). A dialysis solution flows on the other side of these membranes, through which small molecules can diffuse. Molecules and ions diffuse from an area of higher concentration to an area of lower concentration, so the composition of the dialysis fluid is crucial. The concentrations of the molecules or ions that need to be conserved must be at the same concentra-

tion in the dialysis fluid as they are in the blood. The concentrations of molecules and ions that need to be removed from the blood are zero in the dialysis fluid. The total osmotic potential of the dialysis fluid must equal that of the plasma.

About 500 ml of the patient's blood is in the dialysis machine at any one time, and the unit processes several hundred milli-

52.14 Renal Dialysis Patients with kidney failure can have their blood cleansed of wastes by renal dialysis machines. Blood flows through channels of semipermeable membranes that allow diffusion of waste molecules from the blood to a dialysis fluid.

liters of blood per minute. A patient with no kidney function must be on the dialysis machine for 4 to 6 hours three times a week.

52.5 RECAP

The anatomical organization of the nephrons makes it possible for the mammalian kidney to produce a urine more concentrated than the blood, thereby conserving water to maintain extracellular fluid volume. Bulk reabsorption of salts, other valuable solutes, and water takes place in the proximal convoluted tubule. The loops of Henle act as a counter-current multiplier, creating a concentration gradient of the interstitial fluids in the renal medulla. Collecting ducts run through the renal medulla and lose water osmotically to the surrounding interstitial fluids, concentrating the urine.

- Explain how the countercurrent multiplier mechanism of the nephron makes it possible for the kidney to form a concentrated urine. **See p. 1102 and Figure 52.10**
- How does the kidney contribute to acid–base balance? **See pp. 1104–1105 and Figure 52.13**

The kidney contributes to homeostasis in several ways, including regulating extracellular fluid volume, maintaining the osmotic concentration and ionic composition of the extracellular fluid, and regulating pH. As we will see next, the kidneys also play a major role in regulating blood pressure.

52.6 How Are Kidney Functions Regulated?

Several regulatory mechanisms act on the kidneys to maintain blood pressure, blood osmolarity, and blood composition. We will discuss these mechanisms separately, but keep in mind that they are always working together.

Glomerular filtration rate is regulated

If the kidneys stop filtering blood, they cannot accomplish any of their functions. The maintenance of a constant **glomerular filtration rate (GFR)** depends on an adequate blood supply to the kidneys at an adequate blood pressure. Renal arteries usually deliver blood to the kidneys at high pressure because they are early branches off the aorta. In addition, *autoregulatory mechanisms* ensure adequate blood supply and blood pressure for kidney function regardless of what is happening elsewhere in the body. The kidney's autoregulatory adjustments compensate for decreases in cardiac output or decreases in blood pressure so that the GFR remains constant.

One autoregulatory mechanism is the dilation (expansion) of the afferent renal arterioles when blood pressure falls. This dilation decreases the resistance in the arterioles and helps maintain blood pressure in the glomerulus. If arteriole dilation

does not keep the GFR from falling, the kidney releases an enzyme, **renin**, into the blood. Renin converts a circulating protein, angiotensinogen, into angiotensin I, which is then acted on by angiotensin converting enzyme (ACE) to form the active hormone angiotensin II, or simply, **angiotensin (Figure 52.15)**. Angiotensin has several effects that help restore the GFR to normal:

- It constricts the efferent renal arterioles, raising the resistance for blood leaving the glomerulus. Like putting a finger over the end of a garden hose, this restriction of drainage elevates blood pressure in the glomerular capillaries.
- It constricts peripheral blood vessels all over the body, an action that elevates central blood pressure.
- It stimulates the adrenal cortex to release the hormone **aldosterone**. Aldosterone stimulates sodium reabsorption by the kidney, thereby making its reabsorption of water more effective. Enhanced water reabsorption helps maintain blood volume and therefore central blood pressure.
- It acts on the brain to stimulate thirst. Increased water intake in response to thirst increases blood volume and blood pressure.

Thus the renin-angiotensin-aldosterone system, or RAAS, coordinates many responses to maintain blood pressure and kidney function.

Blood osmolarity and blood pressure are regulated by ADH

Cells in the hypothalamus can stimulate the release from the posterior pituitary of a hormone called *antidiuretic hormone (ADH)*, also called *vasopressin* that can act on cells of the collecting duct to insert aquaporins (water channels) into their plasma membranes. The aquaporins increase the permeability of these membranes to water, and therefore more water is reabsorbed from the collecting duct fluid into the interstitial spaces of the renal medulla. The higher the circulating levels of ADH, the greater the number of aquaporins. Various factors can stimulate or inhibit the release of ADH. Of key importance to kidney function are osmoreceptors that monitor blood osmolarity and stretch receptors that monitor blood pressure (**Figure 52.16**).

Osmoreceptor neurons in the hypothalamus are activated by a rise in blood osmolarity, and they increase the release of ADH. ADH helps regulate blood osmolarity by controlling water reabsorption. The osmoreceptors also stimulate thirst. The resulting water retention and water intake dilute the blood as they expand blood volume.

Stretch receptors in the walls of the aorta and the carotid arteries (see Figure 50.17) that detect an increase in blood pressure will *inhibit* the release of ADH. With less circulating ADH, less water is reabsorbed, which decreases blood volume and hence acts to lower blood pressure.

If blood pressure falls, as when you lose blood volume through hemorrhage or excessive evaporative water loss, activity of the stretch receptors in the aorta and carotid arteries decreases. Input via cranial nerves to the hypothalamus from these receptors inhibits the release of ADH, so when the firing rates

52.16 Antidiuretic Hormone Increases Blood Pressure and Promotes Water Reabsorption ADH is produced by neurons in the hypothalamus and released from nerve endings in the posterior pituitary. The release of ADH is stimulated by hypothalamic osmoreceptors and inhibited by stretch receptors in the great arteries. Red lines indicate inhibitory actions; green lines show stimulatory actions.

INVESTIGATING LIFE

52.17 ADH Induces Insertion of Aquaporins into Plasma Membranes

Aquaporin proteins make different regions of renal tubules permeable to water. One of these, AQP-2, is responsible for the permeability of the collecting duct cells. How does antidiuretic hormone act on these proteins to control the level of permeability in renal cells?

HYPOTHESIS Antidiuretic hormone (ADH) controls the location of aquaporin proteins.

METHOD

1. Isolate collecting ducts from rat kidney.
2. Use immunochemical staining to localize the AQP-2 aquaporins in collecting duct cells both with and without the presence of ADH. Also localize the aquaporins after ADH is applied and then washed away.

3. Perfuse collecting ducts and measure water permeability under the same three conditions.

RESULTS

CONCLUSION In the absence of ADH, AQP-2 is sequestered intracellularly. When ADH is present, these water channels are inserted into the plasma membranes, making the cells more permeable to water.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

of these stretch receptors fall, ADH release increases. More ADH results in more efficient water reabsorption and therefore a protection of blood volume and blood pressure.

Alcohol inhibits ADH release, explaining why excessive beer drinking leads to excessive urination and dehydration, which contributes to the symptoms of a hangover.

As mentioned earlier, the presence of aquaporins in plasma membranes determines their water permeability. Aquaporins play an important and unique role in the collecting duct. Several members of the aquaporin family of water channels are found in the plasma membranes of cells in the distal tubules. At least two aquaporins are localized in the basolateral membranes (facing the blood vessels). A different aquaporin, called AQP-2, is found in the apical plasma membranes (facing into the tubule). But the presence of AQP-2 in these membranes is controlled by ADH, as described in **Figure 52.17**.

Sometimes AQP-2 is sequestered in the membranes of intracellular vesicles, and when it is, the collecting duct permeability is low. ADH causes these vesicles to insert their AQP-2 channels into the apical plasma membrane, making that membrane (and therefore the cell) permeable to water. ADH also stimulates the synthesis of new AQP-2 proteins. Thus, circulating ADH controls the number of AQP-2 water channels in the plasma membranes of the collecting duct cells, and therefore their water permeability.

The heart produces a hormone that helps lower blood pressure

You may not think of the heart as an endocrine organ, but it is. When blood volume is high, blood pressure is high, and that puts strain on the heart. Under these conditions, the increased venous return stretches the atria of the heart. When the atrial muscle fibers are overly stretched, they release a peptide hormone called **atrial natriuretic peptide (ANP)**. This peptide hormone enters the circulation, and in the kidney it decreases the reabsorption of sodium. If less sodium is reabsorbed, less water is reabsorbed, and more passes into the urine. Thus, ANP has the effect of lowering blood volume and therefore blood pressure.

52.6 RECAP

Glomerular filtration is essential for kidney function and is sustained by autoregulatory mechanisms. Sensors that monitor blood pressure and blood osmolarity may stimulate or inhibit the release of hormones that regulate kidney function.

- Explain how falling GFR results in an increase in circulating angiotensin and how angiotensin restores GFR. **See p. 1107**
- Explain how falling blood pressure or increasing blood osmolarity result in changes in permeability of the collecting ducts. **See Figure 52.16**

CHAPTER SUMMARY

52.1 How Do Excretory Systems Maintain Homeostasis?

- **Excretory systems** maintain the osmolarity and volume of the extracellular fluids and eliminate the waste products of nitrogen metabolism through the processes of filtration, reabsorption, and secretion. **Urine** is the output of excretory systems.
- There is no active transport of water, so water must be moved across membranes by a difference in either **osmolarity** or pressure.
- Water enters or leaves cells by osmosis. To achieve cellular water balance, animals must maintain the osmolarity of their extracellular fluids within an acceptable range.
- Marine animals can be **osmoconformers** or **osmoregulators**. Freshwater animals must be osmoregulators and must continually excrete water and conserve salts. Most animals are ionic regulators to some degree.
- Apart from regulating osmolarity of cells and extracellular fluids, most animals must also regulate their ionic composition by conserving some ions and secreting others. Salt glands are adaptations for secretion of NaCl. **Review Figure 52.2**

52.2 How Do Animals Excrete Nitrogen?

- Aquatic animals that breathe water can eliminate nitrogenous wastes such as **ammonia** by diffusion across their gill membranes. Terrestrial animals and some aquatic animals must detoxify ammonia by converting it to **urea** or **uric acid** before excretion. **Review Figure 52.3**
- Depending on the form in which they excrete their nitrogenous wastes, animals are classified as **ammonotelic**, **ureotelic**, or **uricotelic**.

52.3 How Do Invertebrate Excretory Systems Work?

- The **protonephridia** of flatworms consist of flame cells and excretory tubules. Extracellular fluid is filtered into the tubules, which process the filtrate to produce a dilute urine. **Review Figure 52.4**
- In annelid worms, blood pressure causes filtration of the blood across capillary walls. The filtrate enters the coelomic cavity, where it is taken up by **metanephridia**, which alter the composition of the filtrate by active transport mechanisms. **Review Figure 52.5, WEB ACTIVITY 52.1**
- The **Malpighian tubules** of insects receive ions and nitrogenous wastes by active transport across the tubule cells. Water follows by osmosis. Ions and water are reabsorbed from the rectum, so the insect excretes semisolid wastes. **Review Figure 52.6**

52.4 How Do Vertebrates Maintain Salt and Water Balance?

- Marine and terrestrial animals conserve water in various ways. Marine bony fishes produce little urine. Cartilaginous fishes retain urea so that the osmolarity of their body fluids remains close to that of seawater. Amphibians remain close to water. Reptiles have skin with low water permeability, lay shelled eggs, and excrete nitrogenous wastes as uric acid.

- Mammals produce urine more concentrated than their extracellular fluids.
- The **nephron**, the functional unit of the vertebrate **kidney**, consists of a **glomerulus**, in which blood is filtered, a **renal tubule**, which processes the filtrate into urine to be excreted, and a system of **peritubular capillaries**, which surround the tubule and serve as a site of secretion and reabsorption. **Review Figure 52.7, WEB ACTIVITY 52.2**

52.5 How Does the Mammalian Kidney Produce Concentrated Urine?

- The concentrating ability of the mammalian kidney is a function of its anatomy, which is ideal for countercurrent exchange. **Review Figure 52.9, ANIMATED TUTORIAL 52.1**
- The glomeruli and the **proximal** and **distal convoluted tubules** are located in the **cortex** of the kidney. Certain molecules are actively reabsorbed from the glomerular filtrate by the tubule cells, and other molecules are actively secreted. Straight sections of renal tubules called **loops of Henle** and **collecting ducts** are arranged in parallel in the **medulla** of the kidney. **SEE WEB ACTIVITY 52.3**
- Salts and water are reabsorbed in the proximal convoluted tubule without the renal filtrate becoming more concentrated, although its composition changes.
- The loops of Henle create a concentration gradient in the interstitial fluid of the renal medulla by a **countercurrent multiplier** mechanism. Urine flowing down the collecting ducts to the **ureter** is concentrated by the osmotic reabsorption of water caused by the concentration gradient in the surrounding interstitial fluid. **Review Figure 52.10**
- Hydrogen ions secreted by the renal tubules are buffered in the urine by bicarbonate and other chemical buffering systems. **Review Figures 52.12 and 52.13**

52.6 How Are Kidney Functions Regulated?

- Kidney function in mammals is controlled by autoregulatory mechanisms that maintain a constant high **glomerular filtration rate (GFR)** even if blood pressure varies.
- An important autoregulatory mechanism is the release of **renin** by the kidney when blood pressure falls. Renin activates **angiotensin**, which causes the constriction of efferent glomerular arterioles and peripheral blood vessels, causes the release of **aldosterone** (which enhances water reabsorption), and stimulates thirst.
- Changes in blood pressure and osmolarity influence the release of antidiuretic hormone (ADH), which controls the permeability of the collecting duct to water and therefore the amount of water that is reabsorbed from the urine. ADH stimulates the expression of and controls the intracellular location of aquaporins, which serve as water channels in the membranes of collecting duct cells. **Review Figures 52.16 and 52.17**
- When the volume of blood returning to the heart increases and stretches the atrial walls, **atrial natriuretic peptide (ANP)** is released, which causes increased excretion of salt and water.

SEE WEB ACTIVITY 52.4 for a review of the major human organ systems.

SELF-QUIZ

- Which statement is *true*?
 - Most marine invertebrates are osmoregulators.
 - All freshwater invertebrates are osmoconformers.
 - Marine bony and cartilaginous fishes have similar interstitial osmolarities.
 - Freshwater fishes are ionic regulators.
 - Marine mammals gain water osmotically.
- The excretion of nitrogenous wastes
 - by humans can be in the form of urea and uric acid.
 - by mammals is never in the form of uric acid.
 - by marine fishes is mostly in the form of urea.
 - does not contribute to the osmolarity of the urine.
 - requires more water if the waste product is the rather insoluble uric acid.
- How are earthworm metanephridia like mammalian nephrons?
 - Both process coelomic fluid.
 - Both take in fluid through a ciliated opening.
 - Both produce urine more concentrated than the blood.
 - Both employ tubular secretion and reabsorption to control urine composition.
 - Both involve a countercurrent multiplier effect.
- What is the role of renal podocytes?
 - They prevent red blood cells and large molecules from entering the renal tubules.
 - They reabsorb most of the glucose that is filtered from the plasma.
 - They control the glomerular filtration rate by changing the resistance of renal arterioles.
 - They provide a large surface area for tubular secretion and reabsorption.
 - They release renin when the glomerular filtration rate falls.
- Which of the following are *not* found in a renal pyramid?
 - Collecting ducts
 - Vasa recta
 - Peritubular capillaries
 - Convoluting tubules
 - Loops of Henle
- Which part of the nephron is responsible for most of the difference in mammals between the glomerular filtration rate and the urine production rate?
 - The glomerulus
 - The proximal convoluted tubule
 - The loops of Henle
 - The distal convoluted tubule
 - The collecting duct
- For mammals of the same size, what feature of their excretory systems would give them the greatest ability to concentrate their urine?
 - Higher glomerular filtration rate
 - Longer convoluted tubules
 - Increased number of nephrons
 - More permeable collecting ducts
 - Longer loops of Henle
- Which of the following would *not* be a response stimulated by a large drop in blood pressure?
 - Constriction of afferent renal arterioles
 - Increased release of renin
 - Increased release of antidiuretic hormone
 - Increased thirst
 - Constriction of efferent renal arterioles
- Which statement about angiotensin is *true*?
 - It is secreted by the kidney when the glomerular filtration rate falls.
 - It is released by the posterior pituitary when blood pressure falls.
 - It stimulates thirst.
 - It increases the permeability of the collecting ducts to water.
 - It decreases glomerular filtration rate when blood pressure rises.
- Birds that feed on marine animals ingest a lot of salt, but they excrete most of it by means of
 - Malpighian tubules.
 - rectal salt glands.
 - gill membranes.
 - concentrated urine.
 - nasal salt glands.

FOR DISCUSSION

- Why is it said that the oceans are a physiological desert? For what animals would this apply?
- Persons with uncontrolled diabetes mellitus can have very high levels of glucose in their blood. Why do such individuals have a high level of urine production?
- Inulin is a molecule that is filtered out of the glomerulus but is not secreted or reabsorbed by the renal tubules. If you injected inulin into an animal and after a brief time measured the concentration of inulin in the animal's blood and urine, how could you determine the animal's glomerular filtration rate? Assume that the rate of urine production is 1 milliliter per minute.
- After you did the inulin experiment to measure glomerular filtration rate, how could you use that information to determine whether another substance is secreted or reabsorbed by the renal tubules? Assume you can measure the concentration of that substance in the blood and urine. Urine production is still 1 milliliter per minute.
- Explain what happens with respect to control and regulation of your salt and water balance when you eat a lot of very salty popcorn.
- Review Figure 52.2, noting that the venules and the secretory tubules are arranged in parallel with blood flowing in one direction and the contents of the tubule flowing in the opposite direction. What is the advantage of this arrangement?

ADDITIONAL INVESTIGATION

We mention on p. 1107 that the glomerular filtration rate (GFR) is autoregulated, and this regulation is achieved by control over constriction/dilation of the afferent and efferent renal arterioles. What information could be used in this process? A clue comes from the anatomy of the nephron. When the ascending limb of Henle reaches the cortex, it makes direct contact with the affer-

ent and efferent arterioles of the glomerulus that produced the filtrate flowing in that particular nephron. What aspect of the tubular fluid in the early distal convoluted tubule would reflect changes in the volume of filtrate entering the nephron? How might the cells of the early distal convoluted tubule communicate with the smooth muscle cells of the arterioles?

WORKING WITH DATA (GO TO yourBioPortal.com)

What Kidney Characteristic Determines Urine Concentrating Ability? Since the loops of Henle create the concentration gradient in the renal medulla, it is reasonable to expect that longer loops would make it possible to generate greater concentration gradients and therefore increase the ability to concentrate urine. However, mammals come in many different

sizes and so do their kidneys, so would you expect all big mammals to be able to concentrate their urine more than small mammals? In this exercise, we will explore anatomical data and urine concentration data from many species to see what characteristic of their kidneys relates to their urine concentrating abilities.

53

Animal Behavior

Monkey see, monkey do

Many years ago, scientists studying a troop of macaques (*Macaca fuscata*) on the Japanese island of Koshima lured the monkeys into the open by throwing pieces of sweet potato onto the beach from a passing boat. The monkeys tried to brush the sand off the potatoes, but the pieces remained gritty. One day, a young female named Imo took her sweet potatoes to the water and washed off the sand. Soon her siblings and other juveniles in her playgroup were imitating Imo's new behavior. Then their mothers began washing their potatoes. None of the adult males imitated this behavior, but young males learned the behavior from their mothers and their siblings and continued to wash their potatoes as they grew older.

The scientists were fascinated by the way Imo's creative, insightful behavior spread throughout the population, so they presented the monkeys with a new challenge: they threw wheat onto the beach. Picking wheat grains out of the sand was tedious and difficult. Imo, apparently a prodigy in the macaque world, came up with a solution: she carried handfuls of sand and wheat to the water and threw them in. The sand sank, but the wheat floated, enabling her to skim the grain off the surface and eat it. This efficient feeding behavior spread throughout the population just as washing sweet potatoes had—first to other juveniles, then to mothers, and then from mothers to their male and female offspring.

The macaques of that troop now routinely wash their food. They also play in the ocean, which they never did before, and they have added marine food items to their diet. Clearly, this population of monkeys has a *culture*: a set of invented behaviors shared by members of the population and transmitted through social learning.

Animals also display elaborate behaviors they do not learn. Web spinning by spiders, for example, requires no practice or prior experience. In many spider species, females die immediately after they lay their eggs; the hatching spiderlings never see their mother, her web, or webs spun by other spiders. Yet when they first construct their own webs,

Shared Learned Behaviors Become a Culture

In the space of a single generation, a population of Japanese macaques (*Macaca fuscata*) learned and transmitted a set of behaviors that included washing food, playing in the water, and eating marine food items—a new “culture” of water-related behaviors.

Spiders Are Born Web Designers Each spider performs a stereotypic sequence of movements that results in a species-specific web design. Spiders such as this banded garden spider (*Argiope trifasciata*) are born with this ability, with no need to learn from experience or to model their movements after those of a parent.

they do it perfectly, without the benefit of experience or a model to copy.

Web spinning requires thousands of movements performed in just the right sequence. Most of that sequence is *stereotypic*—performed the same way every time. Different spider species spin webs of different designs, using different sequences of movements. Yet every spider knows how to spin its species-specific web at birth; the behavior is part of its genetic inheritance.

Most animal behavior stems from an interaction of genetic inheritance and learning, and modern studies of animal behavior focus on the mechanisms of both. The evolution of behavior is also a topic of great interest, and research on that topic asks how particular behaviors are adaptive in specific environments. In short, behavioral biology is a highly integrative field that incorporates approaches from virtually all of the biological subdisciplines you have studied in this book.

IN THIS CHAPTER we will describe how the modern study of animal behavior emerged from earlier research focused on learning and on inherited behavior. We will give examples of how methods from genetics and molecular genetics, physiology, neurobiology, ecology, and evolution have contributed to our understanding of the behavior of animals—including ourselves.

CHAPTER OUTLINE

- 53.1** What Are the Origins of Behavioral Biology?
- 53.2** How Can Genes Influence Behavior?
- 53.3** How Does Behavior Develop?
- 53.4** How Does Behavior Evolve?
- 53.5** What Physiological Mechanisms Underlie Behavior?
- 53.6** How Does Social Behavior Evolve?

53.1 What Are the Origins of Behavioral Biology?

Humans have studied animal behavior since prehistoric times. Understanding the habits of potential prey, as well as those of their predators, was of great value to hunters. Appreciation of behavioral traits led to the domestication of animal species. Accounts of dramatic animal behaviors such as seasonal appearances and disappearances, mating displays, aggression, prey capture, and even less dramatic behaviors such as parental care, communication, and sleep are found throughout recorded history. Yet the scientific study of animal behavior did not truly get under way until the early 1900s.

Conditioning was the focus of behaviorists

The discovery of the *conditioned reflex*, a simple form of learning, by the Russian physiologist Ivan Pavlov in the late 1800s was a seminal event. Pavlov was studying the neural control of digestive juice secretion, and he observed that a dog salivated when it smelled food. He also noticed that the dog salivated when the technician who normally fed the dog entered the room even when no food was present. Following up this observation, he substituted a sound stimulus for the technician. When the dog was fed, a metronome ticked. After a number of trials, the dog salivated when it heard the metronome even if no food was offered. Pavlov showed that other sounds worked as well (including a bell, which is commonly associated with his work).

Salivation in response to the sight, smell, or taste of food is a natural reflex response to a stimulus, but salivation in response to a sound was a learned response. The pairing of a sound with the experience of receiving food *conditioned* the dog's nervous system to generate a response, which Pavlov dubbed the **conditioned reflex**. The food was referred to as the *unconditioned stimulus* (US), and the sound as the *conditioned stimulus* (CS) (**Figure 53.1**). Thus Pavlov showed that a simple behavior controlled by the nervous system could be modified through experience.

Pavlov received a Nobel prize in 1904, and his work stimulated much new research because he had developed an experimental model of learning. All sorts of changes in the relationship between a CS and a US were investigated. A particularly interesting variation was developed by the psychologist B. F. Skinner, who showed that any random action of an animal could become a conditioned response to a stimulus if a reward was temporally associated with the action and the stimulus. For example, a rat could be conditioned to press a lever in response to a stimulus if it got a reward when it behaved as the experi-

(A) Before conditioning

(B) Conditioning

(C) After conditioning

menter desired. Because the animal was conditioned to perform an operation on its environment, this experimental protocol was known as **operant conditioning** and was viewed as another model of learning.

The experimental approach to behavior initiated by Pavlov and Skinner had powerful effects on the nature of research on animal behavior. The focus of scientists using this approach was quite specific:

- They focused on laboratory environments rather than natural environments because in the laboratory, the variables in their conditioning experiments could be precisely controlled.
- They focused on only a few species (predominantly the albino rat) as model systems rather than studying diverse species from nature.

53.1 The Conditioned Reflex Ivan Pavlov discovered that when a normal response is paired with an artificial stimulus, an animal learns to produce the response even when only the artificial stimulus is presented.

- They focused on questions of learning and memory, largely to the exclusion of other types of behavior (e.g., mating, feeding, communication).

Thus defined, the field of animal behavior research became known as **behaviorism**, and it was largely the domain of psychologists.

Fixed action patterns were the focus of ethologists

An alternative approach to the study of animal behavior arose at the same time as behaviorism, but largely in Europe. Scientists there focused on describing the characteristics of animals in their natural environment, an approach that became known as **ethology** (Greek *ethos*, “character”; *logos*, “study”). In contrast to the behaviorists, the ethologists were interested in a wide variety of species, their evolutionary relationships, and the ways in which their behaviors were adapted to their environments. The leaders of the ethology movement were Karl von Frisch, who discovered the dance language of bees; Konrad Lorenz, who discovered that the strong bond between parent and offspring develops during a “critical period” following birth; and Niko Tinbergen, who studied inborn patterns of behavior commonly known as instincts. These three scientists shared the Nobel Prize in 1973 for “their discoveries concerning organization and elicitation of individual and social behavior patterns.”

The instinctive behaviors that were the main interest of the ethologists were genetically determined patterns. Genetically determined behaviors

- are performed without learning
- are *stereotypic* (i.e., performed the same way each time)
- cannot be modified by learning

The ethologists called such behaviors **fixed action patterns**.

To demonstrate that a behavior was genetically determined, ethologists performed **deprivation experiments** in which an animal was raised in an environment devoid of opportunities to learn its species-specific behavior. An example of a natural deprivation experiment is the web spinning of the spider featured at the opening of this chapter. The parents of the young spider die before it hatches, and in a seasonal environment, it has no model webs to copy when it spins its first web, yet it creates a perfect, species-specific web the first and every time it spins a web.

Fixed action patterns are usually responses to specific stimuli. The ethologists carefully characterized such stimuli, which they called **releasers**. In general, releasers are very simple subsets of the information available in the environment. For example, Tinbergen studied the begging behavior of gull chicks. Adult gulls have a red dot on their bills. When a parent gull returns to the nest to feed its chicks, the chicks peck on the red

53.2 Releasing a Fixed Action Pattern (A) Gull chicks instinctively peck at the red dot on the parent's lower bill, a behavior that induces the parent to regurgitate food into the chick's mouth. (B) Tinbergen's work showed that the red dot on the parent's beak was the critical component that released the pecking response.

dot, which stimulates the parent to regurgitate food (**Figure 53.2A**). Experimenters investigated what stimulated the chicks to peck their parents' bills. Models of gull heads of different shapes and colors were tested (**Figure 53.2B**), as were models of a beak without a head. The results showed that the red dot was necessary for the release of chick pecking behavior. In fact, a pencil with a red eraser elicited a more robust pecking response than an accurate model of a gull head without a red dot.

Ethologists probed the causes of behavior

The ethologists demonstrated the genetic basis for fixed action patterns by interbreeding closely related species. Konrad Lorenz studied the courtship behaviors of different species of dabbling ducks. Some of these species, such as mallards, teals, pintails, and gadwalls, are closely related and can interbreed, but they rarely do so in nature. Each male duck performs a courtship display consisting of a precise series of movements that is typical of his species (**Figure 53.3**). A female is not likely to accept him unless the entire display is successfully and correctly completed.

When Lorenz crossbred these duck species, the hybrid offspring expressed some elements of each parent's courtship display,

but in novel combinations. Furthermore, Lorenz observed that hybrids sometimes exhibited display elements that were not in the repertoire of either parent species but were seen in other dabbling duck species. Lorenz's interbreeding studies demonstrated that the stereotypic motor patterns of the courtship displays are inherited. The observation that females were not interested in males performing hybrid displays was evidence that *sexual selection* (see Section 21.3) had shaped these genetically determined behaviors.

The ethologists recognized the importance of development and motivation in behavior, and they laid the foundation for the application of modern biological methods to the study of animal behavior. Tinbergen outlined the challenges for investigators as four questions:

- **Causation:** What is the stimulus for the behavior, and how has the relationship between stimulus and behavior been modified by learning?
- **Development:** How does the behavior change with age, and what experiences are necessary for it to be displayed?

53.3 Courtship Displays Are Highly Specific The courtship display of the male mallard (*Anas platyrhynchos*) contains the precise 10 elements illustrated here. The displays of closely related dabbling duck species contain some of the same elements, but have other elements not displayed by mallards.

- *Function*: How does the behavior affect the animal's chances for survival and reproduction?
- *Evolution*: How does the behavior compare with similar behaviors in related species, and how might it have evolved?

The first two questions refer to the **proximate causes** of behavior: the immediate genetic, physiological, neurological, and developmental mechanisms that determine how an individual is behaving at a particular time. The third and fourth questions refer to the **ultimate causes** of behavior: the evolutionary processes that produced the animal's capacity and tendency to behave in particular ways. In the sections that follow, we will describe many experiments on animal behavior. For each one, ask yourself which of Tinbergen's four questions it addresses and whether it focuses on proximate or ultimate causes of behavior.

53.1 RECAP

Early scientific studies of animal behavior took two approaches. Behaviorists focused on the study of conditioned behavior in a few species of laboratory animals and asked questions about learning. Ethologists studied genetically determined behavior in many species in their natural environments and asked evolutionary questions.

- Describe the difference between conditioned reflexes and operant conditioning. **See pp. 1114–1115 and Figure 53.1**
- What is the relationship between a releaser and a fixed action pattern? **See p. 1115 and Figure 53.2**
- Explain the difference between proximate and ultimate causes of behavior and how Tinbergen's questions address these two types of causes. **See pp. 1116–1117**

The work of the ethologists left no doubt that behavior can be genetically determined, but how? Genes code for proteins. Behaviors are highly complex traits involving sensory input and intricate patterns of control over responses to that input. Is it reasonable to think that a single gene can have a specific effect on a behavior?

53.2 How Can Genes Influence Behavior?

Behaviors are complex traits that depend on many genes. Nevertheless, evidence from multiple approaches shows that alterations in single genes can result in discrete behavioral phenotypes on which natural selection can operate.

Breeding experiments can show whether behavioral phenotypes are genetically determined

Behavioral geneticists identify individuals with unusual behavioral phenotypes and conduct breeding experiments to see if

those traits are inherited. If the inheritance of a trait follows a Mendelian inheritance pattern (see Section 12.1), then that trait is likely to be controlled by a small number of genes. A classic example is the genetics of hive cleaning by honey bees.

As we saw at the opening of Chapter 43, a honey bee colony consists of a reproductive queen bee and a huge number of non-reproductive workers. The worker bees have many tasks to perform. The queen deposits eggs in cells of the honeycomb structure that the workers construct. The eggs hatch into larvae, which are fed in their cells by workers. When the larvae are ready to pupate, the workers cap and seal their cells. If a pupa dies before emerging as an adult, workers will normally uncap the cell and drag the carcass outside the hive. This *hygienic* behavior increases the resistance of the hive to a bacterium that infects and kills bee larvae. Some hives do not show this behavior; these *nonhygienic* hives are more susceptible to the spread of this disease.

When a nonhygienic female bee was crossed with a hygienic male, the offspring were all nonhygienic, indicating that the genetic determinant of nonhygienic behavior is dominant. When these nonhygienic F₁ offspring were backcrossed to hygienic males, however, four phenotypes were produced. Two phenotypes were like those of the parents, either hygienic or nonhygienic, but the other two showed interesting deficits. One phenotype opened the cells of dead pupae, but did not remove them. The other phenotype did not open cells, but if a cell was already open, it would dispose of the dead pupa (**Figure 53.4**). Thus the complex hygienic behavior has at least two components that are controlled by separate genes. But the physical identity of these genes, and how they influence the behavior, could not be revealed by breeding experiments.

Knockout experiments can reveal the roles of specific genes

Some modern molecular genetic approaches start with identified genes and eliminate or silence them to see what effects their elimination has on a behavioral phenotype (see Section 18.4). As you might expect, knocking out genes involved in sensory pathways can have pronounced effects on behavior. One example is a gene for a specific olfactory receptor in mice.

As we saw in Section 46.2, mice have two olfactory organs: the nasal olfactory epithelium common to all mammals, and a small organ in the nasal passages, called the *vomerolnasal organ*, or VNO (**Figure 53.5**). Catherine Dulac at Harvard University discovered that a large number of pheromone receptors were expressed in that organ. (As described in Section 46.2, *pheromones* are signaling molecules released into the environment.) Dulac hypothesized that when the receptors in the male's VNO bound to sex pheromones produced by female mice, they stimulated mating behavior. To test this hypothesis, Dulac created a genetically engineered male mouse in which the gene for an ion channel necessary for VNO receptor signaling was knocked out. Contrary to the prediction of the hypothesis, the knockout males in fact did pursue and mate with females placed in their cages. However, they also pursued and tried to mate with *males* placed in their cages. Normally a male mouse

53.4 Genes and Hygienic Behavior Some worker honey bees remove carcasses of dead pupae from their hive. Two components of this behavior—cell uncapping and removal of the carcass—are under the control of separate recessive genes, designated u and r .

53.5 The Mouse Vomeronasal Organ Identifies Gender (A) The mouse VNO is located adjacent to the nasal passages. It contains pheromone receptors whose input travels to a specific region of the olfactory bulb (the accessory olfactory bulb). (B) In mice, information from the VNO appears to be crucial in identifying gender and thus a potential sexual partner.

reacts aggressively to a strange male, but the knockout male could not discriminate between males and females placed in his cage. Thus properly functioning VNO receptors appear to be essential not for sexual attraction, but for gender identification. It is possible to imagine how selection working on this one gene could modify the intensity of male–male aggression and lead to changes in social behavior.

Behaviors are controlled by gene cascades

Male courtship behavior in *Drosophila melanogaster*, the laboratory fruit fly, is stereotypic, species-specific, and requires no learning—a classic fixed action pattern. When a male encounters a potential mate, he follows her, taps her body with his foreleg, extends and vibrates one wing, and licks her genitals (**Figure 53.6A**). The development of this complex male behavior is under the control of a single gene, called *fruitless* (*fru*), just as the development of male anatomy is under the control of another gene, called *doublesex* (*dsx*). In both males and females, these two genes are part of a gene expression cascade that results in different *dsx* and *fru* gene products in males and females (**Figure 53.6B**). The female version of the Dsx protein controls the development of female anatomy, and the expression of *fru* in the male nervous system results in the organization of the neural circuitry controlling male sexual behavior.

There are two take-home lessons from this example. First, genes that control aspects of behavior, like other genes, are generally embedded in gene cascades that offer multiple opportunities for simple genetic changes that will alter the phenotype of even complex behaviors. Second, certain genes, such as *dsx* and *fru*, influence a whole range of genes that contribute to complex behaviors. Modifications in any one of those genes or its ex-

53.6 The fruitless Gene (A) Male fruit flies display stereotypic, species-specific courtship behavior. (B) Sexual differentiation in *Drosophila* is controlled by a cascade of genes, including the *fru* gene, whose expression results in male sexual behavior.

pression can alter behavior. Thus, even though no behavior is coded for by a single gene, alterations in single genes can influence behavior in ways that affect an animal's fitness.

53.2 RECAP

Breeding experiments show that behavioral phenotypes can be inherited and modified by natural selection. Although most behaviors are controlled by complex cascades of genes, molecular genetic methods have shown that a single, identifiable gene in the cascade can control a complex behavior.

- How did breeding experiments on honey bees show the genetic basis for hygienic behavior?
See p. 1117 and Figure 53.4
- What is the evidence that the vomeronasal organ in mice is responsible for gender identification?
See pp. 1117–1118
- Describe some of the different ways a gene can control expression of a complex behavior.
See p. 1118 and Figure 53.6

How can the genetic cascades that underlie complex behaviors be programmed to respond selectively to specific sets of stimuli? How can their expression be limited to appropriate times in an animal's life? The answers to these questions can be found by studying how behaviors develop over the life span.

53.3 How Does Behavior Develop?

The emergence of behavior as an animal develops and matures depends on the development of the nervous system as well as on the growth and maturation of other body systems. A bird cannot fly until its wings grow and its muscles and flight feathers mature. But even with anatomical and physiological competence, specific behaviors may not be expressed. Behaviors that are adaptive at one stage in an animal's life may not be adaptive at other stages. Behaviors typical of juvenile animals, such as begging for food, may disappear and new behavior patterns of a mature individual, such as courtship displays, appear.

Hormones can determine behavioral potential and timing

Hormones can determine the development of a behavioral potential at an early age and the expression of that behavior at a later age. An excellent example of this is sexual behavior in rats

(A) Female rats

(B) Male rats

53.7 Hormonal Control of Sexual Behavior Experimental hormonal treatments of rats demonstrated that the sex steroids present during early development determine what sexual behavior patterns develop, but the sex steroids present in adulthood control the expression of those patterns.

(Figure 53.7). Normally, adult male and female rats exhibit different patterns of sexual behavior: females adopt a sexually receptive posture, called *lordosis*, in the presence of males, and males copulate with receptive females. Neither sex, however, expresses these behaviors until the animals have reached adulthood. Experiments in which newborn and adult rats were neutered (to remove the influence of sex steroids naturally produced by their gonads) and artificially treated with hormones led to the following conclusions:

- Development of male sexual behavior requires that the brain of the newborn rat be exposed to testosterone, but development of female sexual behavior does not require exposure to estrogen.
- Testosterone masculinizes the nervous systems of both genetic males and genetic females.
- Exposure to sex steroids in adulthood is necessary for the expression of sexual behavior, but testosterone produces male sexual behavior only in adult rats whose brains were masculinized when they were newborns, and estrogen produces female sexual behavior only in adult rats whose brains were not masculinized when they were newborns.

Thus, the sex steroids that are present at birth determine which pattern of behavior develops, and the sex steroids that are present in adulthood determine when that pattern is expressed.

Some behaviors can be acquired only at certain times

Responsiveness to simple releasers is sufficient for certain behaviors such as begging behavior in gull chicks, but more complete information that cannot be genetically programmed is required for other behaviors. An example is parent–offspring recognition. When animals live in close proximity to other individuals, as in a herd or a nesting colony, it is important for a mother and her offspring to learn each other’s identity soon after birth so they will be able to find each other in a crowded situation. In many such cases, a parent–offspring bond is formed by **imprinting**. What characterizes imprinting is that an animal learns a specific set of stimuli during a limited time called a **critical period** or **sensitive period**.

Konrad Lorenz demonstrated that young goslings imprint on their parents between 12 and 16 hours after hatching. By positioning himself to be present during this critical period, Lorenz succeeded in imprinting goslings on himself. The imprinted goslings followed him around as if he were their parent (Figure 53.8A).

Imprinting requires only a brief exposure, but its effects are strong and long-lasting. Emperor penguins reproduce during the coldest, darkest time of year in Antarctica. The parents walk up to 150 km inland to form a dense colony, where the female lays her egg. She then walks back to the ocean to feed while her

(A)

(B)

53.8 Imprinting Helps Parents and Offspring Recognize Each Other (A) Greylag geese that imprinted on Konrad Lorenz as hatchlings followed him everywhere he went. (B) Imprinting allows a male emperor penguin to find his own chick among many others.

mate incubates the egg. By the time she returns, the chick has hatched. She then takes over its care and feeding, and the father walks back to the ocean to feed. Generally, he is away so long that the mother must leave to find food as well to avoid starvation. Thus, after being away for weeks, the father must find his chick in a crowded, milling colony of chicks, all calling for their parents (**Figure 53.8B**). Yet he can unerringly locate his own offspring by recognizing its call, which he learned before he left to feed.

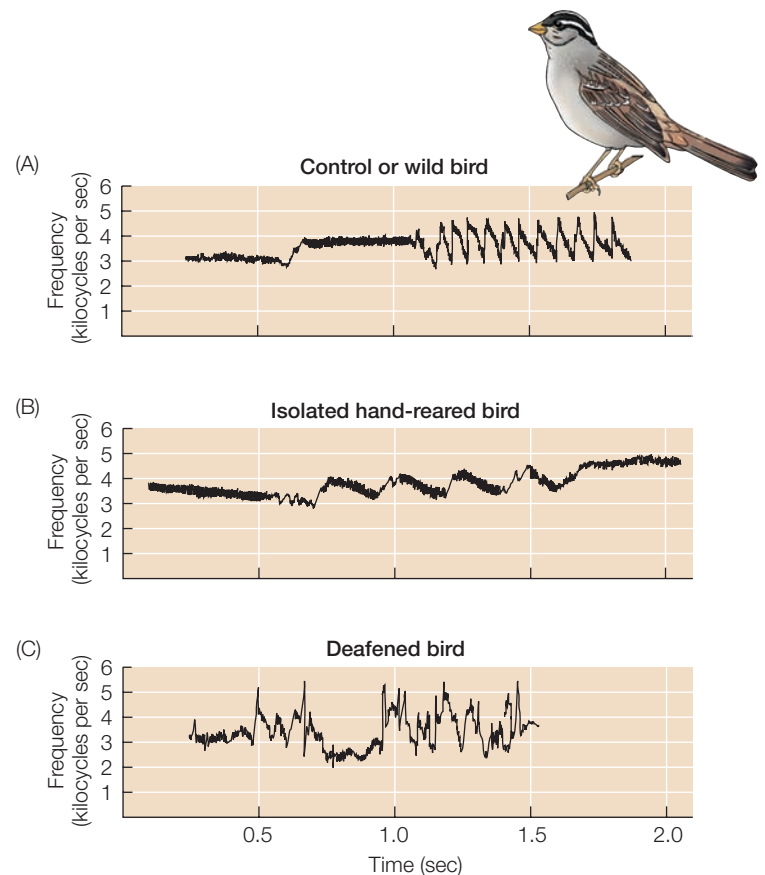

The critical or sensitive period for imprinting may be determined by a brief developmental or hormonal state. For example, if a mother goat does not nuzzle and lick her newborn within 10 minutes after its birth, she will not recognize it as her own offspring later. For goats, the sensitive period is associated with peaking levels of the hormone oxytocin in the mother's circulatory system at the time she gives birth and is sensing the olfactory cues emanating from her newborn kid. A female goat rendered incapable of smelling before giving birth is unable to differentiate between her own kid and other kids after giving birth.

Bird song learning involves genetics, imprinting, and hormonal timing

Male songbirds use species-specific song to claim and advertise a breeding territory, compete with other males, and declare

dominance. They also use song to attract females, who recognize the song of their species even though they do not sing it. For males of many species, such as the white-crowned sparrow, learning is an essential step in the acquisition of song, but *what* they can learn seems to be influenced by genes, and there is a limited *developmental time frame* for learning. A hatchling in nature hears his father and other white-crowned sparrows singing. He also hears the songs of many other bird species. But he does not sing until he approaches sexual maturity almost a year later, and when he does, he sings his father's type of song.

Studies of song learning in this species were initiated in the 1960s by Peter Marler at the University of California at Berkeley. Marler incubated eggs of white-crowned sparrows and hand-reared the hatchlings in the laboratory. He was therefore able to expose them to different tape-recorded songs at different times in their development. He discovered that male birds cannot produce their species-specific song as adults unless they hear it as nestlings in the first 2 months of their lives (**Figure 53.9**). If the nestlings hear tapes of white-crowned sparrow song during those first 2 months, they begin to sing, but poorly, as they approach sexual maturity. Through trial and error, the birds

53.9 Sensitive Periods for Song Learning (A) Sonogram showing the species-specific song of an adult male white-crowned sparrow (*Zonotrichia leucophrys*). (B) Song of an adult male raised in isolation (never having heard the song as a nestling). (C) Song of an adult male who heard the song as a nestling but was deafened prior to ever singing himself. Marler's experiments showed the bird must first acquire a song memory by hearing the song as a nestling, and must then be able to hear himself as he attempts to match his singing to that song memory.

match their singing to their stored song memory, and from then on they sing their species-specific song. To reach this point, the young bird must be able to hear himself sing. If he is deafened just before he begins to sing, he will not be able to match his stored song memory. If he is deafened *after* he sings his correct species-specific song, however, he will continue to sing like a normal bird. We say that at this point the song behavior pattern is *crystallized*. Thus there are two sensitive periods for song learning: the first in the nestling stage, when a song memory is imprinted; the second as the bird approaches sexual maturity, when he learns to match that song memory.

In nature, nestling male white-crowned sparrows hear the songs of many species, so why do they learn only the song of their own species? Marler investigated this question in his isolation experiments by playing tape recordings of other songs to the hatchlings. The young male sparrows did not learn the songs of other species, even if they heard them many times, but hearing songs of their own species just a few times was sufficient for imprinting. Thus, although male sparrows must learn their song, they seem to have a genetic predisposition to learn their own song and not the songs of other species. Marler called this phenomenon “an instinct to learn.” There is an important reason why male white-crowned sparrows should learn only their species-specific song: female white-crowned sparrows also listen to their fathers’ songs while they are nestlings, and when they mature, they choose mates who sing like their fathers did.

Since Marler’s pioneering work, more investigations have revealed additional complexity in white-crowned sparrow song learning capacity. First, it was demonstrated that each population of white-crowns has its own dialect, and that males from one population can learn the dialect of another population. Second, it was observed that in nature, white-crowns are occasionally heard singing the songs of other species. Could Marler’s laboratory experiments have missed a critical natural variable?

Luis Baptista, a curator of birds at the California Academy of Sciences, took up the study of white-crowned sparrows to explore the effects of social interactions on song learning. He discovered that when a hand-reared white-crowned sparrow nestling was exposed to the sight and sound of a related species in an adjacent cage while tapes of his own species’ song played in the background, the white-crowned sparrow sang the song of the other species when he matured. Thus social experience has a powerful effect on what the young bird can and will learn.

The timing and expression of bird song are under hormonal control

As we have seen, both male and female songbirds hear their species-specific song as nestlings, but only the males of most species sing as adults, and they do so only in spring. Hormones underlie both the difference in song expression between male and female songbirds and the timing of song expression.

To determine whether the absence of testosterone is the main reason female songbirds don’t sing, investigators injected adult

female songbirds with testosterone in spring. In response to these injections, the females sang their species-specific song just as the males did. Apparently females form a memory of their species-specific song when they are nestlings, and have the physical capacity to sing, but under normal circumstances they simply lack the hormonal stimulation.

How does testosterone cause a songbird to sing? A remarkable study revealed that each spring, an increase in circulating testosterone levels causes certain parts of the male’s brain necessary for learning and developing song to grow larger. Individual neurons in those regions of the brain increase in size and grow longer extensions, and the number of neurons in those regions increases. Such research on the neurobiology of bird song revealed that, contrary to the once widely held belief that new neurons are not produced in the brains of adult vertebrates, hormones can control behavior by changing brain structure as well as brain function, both developmentally and in response to environmental cues.

What triggers the release of testosterone in response to the onset of spring? Takashi Yoshimura conducted a DNA microarray analysis of brain samples from another bird species, the Japanese quail, which is a model species for avian genetic analyses. Knowing that photoperiod was the environmental cue, he examined the responses of 38,000 genes to determine which genes were activated by changes in day length. Fourteen hours after dawn on the first day with the critical photoperiod that induces singing behavior, genes in the brain that code for thyroid-stimulating hormone were switched on. This hormone acts on the pituitary gland, which in turn regulates the production of other hormones that stimulate the growth of the testes and the production of testosterone (see Figure 43.10).

53.3 RECAP

Hormones can control what behavior patterns are programmed in the brain long before those behaviors are expressed. Learning and expression of behaviors can also be controlled by hormones, and therefore timed for particular stages in the life cycle.

- What hormonal conditions are necessary for the development of adult sexual behavior in male and female rats? **See pp. 1119–1120 and Figure 53.7**
- What is the adaptive value of imprinting? **See pp. 1120–1121**
- Describe the series of events necessary for a male white-crowned sparrow to sing its species-specific song in spring. **See pp. 1121–1122 and Figure 53.9**

Complex behaviors are the product of interactions of genetic, physiological, and environmental factors. Many genes are involved in shaping behavior, and therefore there are multiple opportunities for selection to favor behavioral modifications. Questions about how changes in behavior adapt animals to environmental conditions are the province of an evolution-based field called *behavioral ecology*.

53.4 How Does Behavior Evolve?

Environmental conditions are highly variable over both time and space. Animal behaviors are also variable within and between species. Behavioral ecologists strive to discover the relationships between behavior and environment with the intent of understanding the evolutionary mechanisms underlying behavior.

Animals must make many behavioral choices

Over an animal's lifetime, its behavior is largely a sequence of choices: where and when to move, where to build a nest, what to eat, when to fight and when to flee, with whom to associate, with whom to mate. Inability to make choices would make it difficult to survive, and making wrong choices reduces its fitness. Behavioral ecologists seek to discover what information animals use to make behavioral choices and how that information relates to aspects of the environment that influence their fitness.

The choice of a place to live, for example, is one that has many consequences for an animal. The environment in which an animal lives is its **habitat**. In most cases the habitat provides not only a protected nest site, but also food and access to mates. In many cases the environmental cues animals use to make their habitat choices are quite simple. For example, seabirds select cliffs or offshore rocks for nesting because those sites offer protection from predators. Animals with very specialized food requirements obviously select habitats where those foods are abundant. The general hypothesis that guides behavioral ecologists is that the cues animals use to select habitats are *reliable predictors of conditions suitable for future survival and reproduction*.

For many species, the presence of **conspecifics**—other members of the same species—is a reliable indicator of the suitability of a particular site for sustaining life. After all, you can't argue with success. Consider the planktonic larvae of marine organisms that drift freely in the water until they initiate a *settling response* that deposits them on the substratum to which they will attach themselves, usually for the rest of their lives. Molecules released into the water by conspecifics can aid larvae in detecting an appropriate substratum, and such molecules induce a settling response in many species.

Observing conspecifics can provide animals with information about the quality of a habitat in other ways. Collared flycatchers (*Ficedula albicollis*) on their breeding grounds in spring are nosy neighbors: they regularly visit the nests of conspecifics. Researchers hypothesized that this behavior allows the flycatchers to assess the quality of the habitat by seeing how well their neighbors are faring. To test this hypothesis, they created some areas with supersized broods—normally an indication of abundant food—by taking young birds from some nests and adding them to nests in another area. The next year, flycatchers preferentially settled in the areas where broods had been artificially enlarged (**Figure 53.10**).

Behaviors have costs and benefits

Behavioral ecologists often use a cost–benefit approach to investigate the relationship between behavior, environment, and

INVESTIGATING LIFE

53.10 Flycatchers Use Neighbors' Success to Assess Habitat Quality

Collared flycatchers (*Ficedula albicollis*) regularly “spy” on other flycatchers in their breeding range. Researchers hypothesized that the birds were gathering information on the reproductive success of already established pairs to help them decide where to settle and breed.

HYPOTHESIS Collared flycatchers will nest at higher densities in areas where their conspecifics appear to have reproduced successfully.

METHOD

1. Transfer nestlings from one territory into nests in another, thereby creating “supersized” broods (an indication of abundant food) in one area and undersized broods in the other. A third research territory is left unaltered to serve as a control.
2. A year later, observe settlement rates (i.e., number of pairs establishing nests) in each territory at the start of the breeding season.

RESULTS

CONCLUSION Collared flycatchers use the brood sizes of already settled conspecifics to assess how good a territory is for breeding.

fitness. A **cost–benefit approach** assumes that an animal has only a limited amount of time and energy, and therefore cannot afford to engage in behaviors that cost more to perform than they bring it in benefits. A cost–benefit approach provides a framework that behavioral ecologists can use to make observations, construct hypotheses, and design experiments to investigate why behavior patterns evolve as they do.

The benefits of a behavior can be measured in terms of the enhancement in fitness an animal accrues by performing the behavior. The cost of a behavior typically has three components:

- **Energetic cost** is the difference between the energy the animal expends performing the behavior and not performing it.

- **Risk cost** is the increased chance of being injured or killed as a result of performing the behavior.
- **Opportunity cost** is the benefit the animal forgoes by not being able to perform other behaviors during the same time interval.

Cost–benefit analysis has been used extensively in the study of **territorial behavior**: aggressive behavior used by an animal to actively deny other animals access to a habitat or resource. Optimal habitats and resources are frequently in short supply, so conspecifics must compete for them. Many animals—usually males—defend all-purpose territories that provide a nest site, food, and access to mates. The territory holder stakes out his boundaries by engaging in aggressive interactions with neighbors, and must then patrol those boundaries constantly and respond to trespassers. These aggressive interactions usually consist of highly stereotypic, species-specific displays such as bird song. Through territorial behavior, the male obtains the resources he needs for reproductive success, but he also pays a price.

Territorial displays require considerable expenditure of energy, they make a male more vulnerable to predation, and they detract from the time he has for feeding or engaging in parental behavior. Michael Moore and Catherine Marler at Arizona State University performed an experiment to estimate the costs incurred by male Yarrow’s spiny lizards (*Sceloporus jarrovi*) when defending a territory (Figure 53.11). These lizards defend territories that include the habitats of several females. Their territorial behavior is normally most intense during September and October, when the circulating testosterone levels of the males are high and the females are most receptive to mating. The researchers varied the intensity of the lizards’ territorial behavior by implanting testosterone capsules in some males in summer, when they are not normally highly territorial.

Testosterone-treated males spent more time patrolling their territories, performed more displays, and expended about one-third more energy than control males (an energetic cost). As a result, they had less time to feed (an opportunity cost), captured fewer insects, stored less energy, and had a higher death rate (a risk cost). In summer, when females are not normally receptive, these high costs of vigorous territorial defense outweigh the reproductive benefits of territoriality. Thus natural selection has favored seasonal variation in the level of the hormone controlling territorial behavior in this species.

GO TO Animated Tutorial 53.1 • The Costs of Defending a Territory

The cost–benefit approach explains the diversity of territorial behaviors seen in different species. Even if a resource is absolutely essential to an animal, if it cannot be defended economically, the animal will not engage in territorial behavior. Food is essential for all animals, but if the food is widely distributed in space or fluctuating in availability, there is no benefit to balance the high costs of trying to defend it. For ex-

INVESTIGATING LIFE

53.11 The Costs of Defending a Territory

By using testosterone implants to increase territorial behavior, Moore and Marler measured the costs to male Yarrow’s spiny lizards (*Sceloporus jarrovi*) of defending a territory during the summer, when they do not normally do so.

HYPOTHESIS Yarrow’s spiny lizards do not defend a territory during summer because the energetic costs of territorial behavior in that season outweigh the benefits.

- METHOD**
1. During the summer, when female lizards are not sexually receptive, insert testosterone capsules under the skin of some males; leave other males untreated as controls.
 2. Observe the patterns of territorial behavior and the survival rate of the two groups of males.

RESULTS

CONCLUSION For these lizards, the cost of defending territories during summer significantly reduces their survival rate without increasing their reproductive success.

53.12 Animals Defend Territories of Different Sizes

(A) The nesting territories of many seabirds consist of only as much space as they can defend without leaving the nest. (B) Male elephant seals fight vigorously to defend areas of beach where females haul out of the water to give birth to their pups. (C) Male sage grouse gather at a lek in Colorado to perform displays aimed at impressing females and winning the opportunity to mate.

ample, the open ocean where seabirds feed cannot be defended. But safe nest sites on islands or rocky cliffs are in short supply, and they can be defended. Thus the territories of seabirds may be no larger than the distance the birds can reach while sitting on their nests (**Figure 53.12A**).

In some cases the resource that is defended is the female herself. Elephant seals spend most of their lives at sea, but females come to land at traditional beach sites to give birth to their pups. Male elephant seals arrive at these sites ahead of time and stake out territories through vigorous fighting (**Figure 53.12B**). When the females arrive on the beaches, they enter the territories of the males. As long as the male territory holder can fend off challengers, he will be able to mate with all the females using his piece of the beach.

The most unusual form of male territorial behavior arises in situations in which neither food, nest sites, nor females are defended. A **lek** is an area where males gather for the purpose of engaging in communal displays of their territorial prowess aimed at impressing females and winning the opportunity to mate. Even though space is not limited, each male defends a small piece of real estate on which he performs a display (**Figure 53.12C**). Those pieces of territory closest to the center of the lek are the prime sites, and males compete intensely for those locations. The females stroll into the lek, observe the males, and generally mate with the males holding the prime sites. The benefit of this system to the female is that she is inseminated by a successful competitor, and therefore her offspring will carry the

genes that contributed to his success. The costs of lekking to males are high, as they engage in continuous, intense territorial behavior that precludes eating, drinking, and sleeping until they are displaced. The benefit is the chance to maximize their fitness by mating with many females.

Cost-benefit analysis can be applied to foraging behavior

Cost-benefit analyses have also been used to investigate the food choices animals make. When an animal *forages* (searches for food), among the decisions it must make are how much time to spend in each location before giving up and moving on, what resources at each location are actually edible, and which of the different types of potential food should be eaten and which should be left alone. By applying cost-benefit approaches to feeding behavior, scientists have produced a body of knowledge known as **optimal foraging theory**, which helps them to identify the fitness value of feeding choices.

The primary benefit of foraging is the nutritional value of the food obtained: the energy, minerals, and vitamins it contains (see Section 51.1). The costs of foraging are similar to those of other behaviors: energy expended, time lost from other activities that could enhance fitness, and the risk of increased exposure to predators.

Animals frequently have to make choices among food items that may differ not only in terms of energy content, but also abundance or ease of acquisition and processing. Optimal foraging theory predicts that in such situations, animals will make choices that will maximize the rate at which they obtain energy. The more rapidly a foraging animal satisfies its energetic requirements, the lower the opportunity costs and risk costs of foraging.

Earl Werner and Donald Hall of Michigan State University performed laboratory experiments with bluegill sunfish to test this energy maximization hypothesis. In preparation for their experiments, they measured the energy content of water fleas (*Daphnia*) of different sizes (the different food types), how much time bluegill sunfish (the foragers) needed to capture and eat

those different food types, the energy they spent pursuing and capturing the different food types, and the rates at which they encountered the different food types under different food densities. Werner and Hall then stocked experimental environments with different densities and proportions of large, medium, and small water fleas. They made two predictions from the energy maximization hypothesis: first, that in an environment with abundant large water fleas, the fish would ignore smaller water fleas; and second, that in an environment stocked with low densities of all three sizes of water fleas, the fish would eat every water flea they encountered. The proportions of large, medium, and small water fleas eaten by the fish under different conditions were close to those predicted by the hypothesis (**Figure 53.13**).

— yourBioPortal.com —

GO TO **Animated Tutorial 53.2 • Foraging Behavior**

The energy maximization hypothesis considers food items in terms of the energy they provide, but animals have nutrient requirements in addition to energy that can play a role in shaping their foraging behavior. Essential minerals, for example, are in short supply in some animals' diets, and those animals may incur large energetic costs and risks to obtain them. Many herbivores and seed eaters, whose food contains low levels of mineral nutrients relative to their needs, obtain those nutrients by eating soil at particular sites where mineral-rich soil is exposed (**Figure 53.14**).

Foods may also be chosen for their medicinal value. Chimpanzees, for example, have been observed eating the pith of a plant called *Vernonia amygdalina*. The pith contains very small quantities of a secondary metabolite called vernonioside B1, which is toxic to chimps at high concentrations, but at low concentrations can kill their intestinal parasites. Chimps that consume this pith have fewer parasites.

INVESTIGATING LIFE

53.13 Bluegill Sunfish Are Energy Maximizers

Based on energy maximization calculations, Werner and Hall predicted (1) that in an environment with abundant large food items (i.e., the water flea *Daphnia*), bluegill sunfish (*Lepomis macrochirus*) would ignore smaller food items and feed preferentially on larger water fleas; and (2) that in an environment where all sizes of *Daphnia* were scarce, the fish would eat every one they encountered. Such a strategy is in keeping with the cost-benefit hypothesis of foraging behavior.

HYPOTHESIS Bluegill food item selection will match the energy maximization predictions of cost-benefit analysis.

METHOD

1. Measure the respective energy content of large, medium, and small water fleas (*Daphnia*).
2. Use cost-benefit energy maximization calculations to predict the rate at which bluegill sunfish will consume the different sized water fleas under different levels of food abundance (i.e., density of water fleas).
3. Provide bluegills with *Daphnia* of different sizes in varying proportions (represented by the different colored bars) and at different densities.

4. Note the proportions of small, medium, and large *Daphnia* actually eaten by the fish under the different conditions and compare these proportions to the predictions of energy maximization.

RESULTS

The food choices made by bluegills match the predictions of the energy maximization hypothesis.

CONCLUSION Bluegills select food items in accordance with the predictions of energy maximization calculations.

53.4 RECAP

Behavioral ecologists seek to explain relationships between variation in behavior and variation in environmental conditions. They seek to discover what information animals use to make behavioral choices and how that information relates to aspects of the environment that influence their fitness. Cost-benefit analysis has been applied to territorial and foraging behavior.

- What might the presence of conspecifics in a habitat tell an animal about that habitat? **See p. 1123 and Figure 53.10**
- Describe three types of territorial behavior and the costs and benefits of each. **See pp. 1124–1125 and Figure 53.11**
- How can cost-benefit analysis be applied to foraging behavior? **See pp. 1125–1126 and Figure 53.13**

Whereas behavioral ecologists are interested in understanding how the natural environment influences the fitness value of behavioral choices—the ultimate causes of those behaviors, in Tinbergen’s terms—other behavioral biologists focus on the physiological mechanisms and principles that underlie behavior—the proximate causes.

53.5 What Physiological Mechanisms Underlie Behavior?

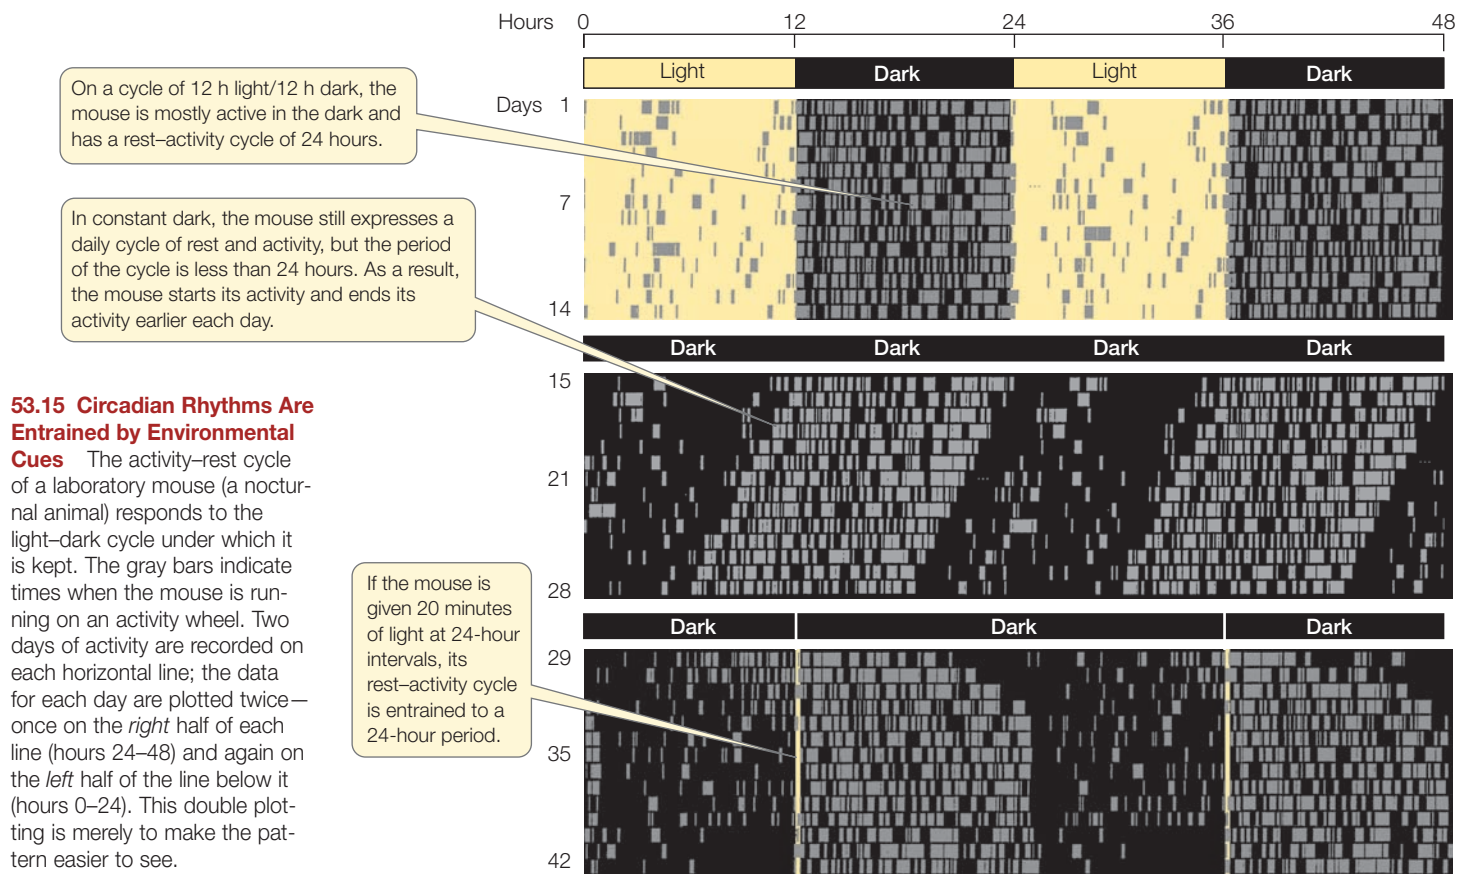

Control of behavior involves the nervous and endocrine systems. Execution of behavior involves the musculoskeletal system as well as other *effector mechanisms*, such as those that produce secretions, color changes, electrical impulses, sound, and even light. We have already considered many of the physiological systems that are involved in these processes, including endocrine mechanisms, reproductive systems, nervous systems, sensory systems, and feeding mechanisms. The field of behavioral physiology, which encompasses aspects of all of these systems, is enormous, so here we will dig deeper into just three different phenomena studied by behavioral physiologists: the timing of behavior, navigation, and communication.

Biological rhythms coordinate behavior with environmental cycles

Earth turns on its axis once every 24 hours, generating daily cycles of light and dark, temperature, humidity, and tides. In addition, Earth is tilted on its axis, so the light–dark cycle changes as it revolves around the sun. These daily and seasonal cycles profoundly influence the physiology and behavior of animals. Animals tend to be either day-active (diurnal) or night-active (nocturnal), and have appropriate sensory capabilities. Therefore it is adaptive to organize behavior on a cycle that corresponds with the environmental cycle of light and dark. Similarly, a behavior that is adaptive at one time of year may not be adaptive at other times. Thus it is important for animals to be able to time their behavior to appropriate times of the day or year and to be able to anticipate those times.

CIRCADIAN RHYTHMS Experimental animals kept in constant darkness and at a constant temperature, with food and water available all the time, still demonstrate daily cycles of activities such as sleeping, eating, drinking, and just about anything else that can be measured. The persistence of these daily cycles in the absence of environmental time cues suggests that animals have an internal clock. Because these daily cycles are not exactly 24 hours long, they are known as **circadian rhythms** (*circa*, “about,” and *dies*, “day”).

As described in Section 37.5, any biological rhythm can be viewed as a series of cycles, and the length of one of those cycles is the *period* of the rhythm. Any point in the cycle is a *phase* of that cycle. Hence, when two rhythms completely match, they are *in phase*, and if a rhythm is shifted (as in the resetting of a clock) it is *phase-advanced* or *phase-delayed*. Because the period of a circadian rhythm is not exactly 24 hours, it must be phase-advanced or phase-delayed each day to remain in phase with

53.15 Circadian Rhythms Are Entrained by Environmental Cues

The activity–rest cycle of a laboratory mouse (a nocturnal animal) responds to the light–dark cycle under which it is kept. The gray bars indicate times when the mouse is running on an activity wheel. Two days of activity are recorded on each horizontal line; the data for each day are plotted twice—once on the *right* half of each line (hours 24–48) and again on the *left* half of the line below it (hours 0–24). This double plotting is merely to make the pattern easier to see.

—yourBioPortal.com

GO TO Animated Tutorial 53.3 • Circadian Rhythms

the daily cycle of the environment. In other words, the rhythm has to be **entrained** to the cycle of light and dark in the animal's environment.

An animal kept under constant conditions will not be entrained to the light–dark cycle of the environment, and its circadian clock will run according to its natural period—it will be *free-running*. If the period is less than 24 hours, the animal will begin its activity a little earlier each day (**Figure 53.15**). The period of the free-running circadian rhythm is under genetic control. Different species may have different average periods, and within a species, mutations can lead to different period lengths.

Under natural conditions, environmental time cues, such as the onset of light or dark, entrain the free-running rhythm to the light–dark cycle of the environment. In the laboratory, it is possible to entrain the circadian rhythms of free-running animals with short pulses of light or dark administered every 24 hours (see the bottom panel of Figure 53.15).

In mammals, the master circadian “clock” consists of two clusters of neurons just above the optic chiasm (the area of the brain where the optic nerves come together). These structures are called the **suprachiasmatic nuclei (SCN)**. If they are destroyed, the animal becomes *arrhythmic*: it is just as likely to eat, drink, sleep, or wake at any time of day.

Martin Ralph (now at University of Toronto) and colleagues, who were then at the University of Virginia, used artificial selection to produce two strains of hamsters: one with a short circadian period and one with a long circadian period. When adult hamsters' SCN were destroyed, the animals became arrhythmic. After several weeks, the scientists transplanted SCN tissue from hamster fetuses into arrhythmic hamsters' brains. The long-period adult hamsters received tissue from short-period fetuses, and vice versa. This experiment produced two remarkable results. First, circadian rhythms were restored by the transplanted SCN tissue, demonstrating that the SCN is sufficient to generate circadian rhythms. This is the only case in which a behavior has been restored by a neural transplant. Second, the restored circadian rhythms had the period length of the donor strain, demonstrating that the specific phenotype of the behavior was a property of the donor neural tissue.

The molecular mechanism of the circadian clock involves negative feedback loops. Although there are a number of genes involved, we can generalize the mechanism by saying that when certain *clock genes* are expressed in SCN cells, the mRNA enters the cytoplasm, where it is translated. The resulting proteins combine and the dimer returns to the nucleus as a transcription factor that shuts off the expression of the clock genes. The period of this cycle is about a day. These findings show that it is possible to understand circadian rhythms of behavior at all levels, from the molecular rhythm generators to the environmental stimuli that entrain them to the daily cycle of light and dark.

CIRCANNUAL RHYTHMS Seasonal changes in the environment present challenges to many species. Most animals reproduce most successfully if they time their reproductive behavior to coincide with the most favorable time of year for the survival of their offspring. Many species require considerable advance preparation for reproduction. Migratory animals must arrive on their breeding grounds at the right time, and animals that have specialized structures used in mating displays, such as the antlers of deer, moose, and caribou, must grow their equipment before the breeding season arrives.

For many species, a change in day length—the *photoperiod*—is a reliable indicator of seasonal changes to come. For others, however, change in day length is not a reliable seasonal cue. Hibernators, for example, spend long months in dark burrows underground, but must be physiologically prepared to breed almost as soon as they emerge in the spring. A bird overwintering near the equator cannot use changes in photoperiod as a cue to time its migration to its temperate-zone breeding grounds. When held under constant laboratory conditions, such animals show endogenous **circannual rhythms**, built-in neural calendars that keep track of the time of year. Unlike circadian rhythms, the neural basis for circannual rhythms is unknown.

Animals must find their way around their environment

To locate suitable habitats, find food and mates, and escape from predators and bad weather, an animal needs to be able to find its way around its environment. Within its local habitat, an animal can organize its behavior spatially by orienting to landmarks. But what if its destination is a considerable distance away?

PILOTING: ORIENTATION BY LANDMARKS Most animals find their way by knowing and remembering the structure of their environment. This form of navigation is called **piloting**. Gray whales, for example, migrate seasonally between the Bering Sea and the coastal lagoons of Mexico (**Figure 53.16**). They find their way in part by following the west coast of North America. Coastlines, mountain chains, rivers, water currents, and wind patterns can all serve as piloting cues for the whales. But some remarkable cases of long-distance orientation and movement cannot be explained by piloting.

HOMING: RETURN TO A SPECIFIC LOCATION The ability to return to a nest site, burrow, or other specific location is called **homing**. Homing can be accomplished by piloting in a known environment, but some animals that travel long distances through unfamiliar territory perform much more sophisticated homing. The ability of pigeons to return to their home loft even after being transported to remote sites is well known. How do they find their way home? Experiments have shown that pigeons use the sun as a compass, but they can still find their way home when the sun is not visible. Other experiments have shown that pigeons equipped with frosted contact lenses can find their way home, suggesting that visual cues are not essential. Most amazing has been the demonstration that pigeons can detect Earth's magnetic field and orient to it much as a human orients with a

53.16 Piloting Gray whales (*Eschrichtius robustus*) migrate south in winter from the Bering Sea to the coast of Baja California by piloting, in part by following the western coast of North America.

compass. Taken together, the studies of homing by pigeons suggest that they can use multiple, redundant sources of directional information and can switch among those sources depending on the circumstances.

MIGRATION AND NAVIGATION OVER GREAT DISTANCES For as long as humans have inhabited temperate latitudes, they have been aware that whole populations of animals, especially birds, disappear and reappear seasonally. Not until the early nineteenth century, however, were patterns of migration traced by marking individual birds with identification bands around their legs. Only when individuals could be unmistakably identified was it possible to show that the same birds and their offspring returned to the same breeding grounds year after year, and that these same birds could be found during the nonbreeding season at locations hundreds or even thousands of kilometers from their breeding grounds.

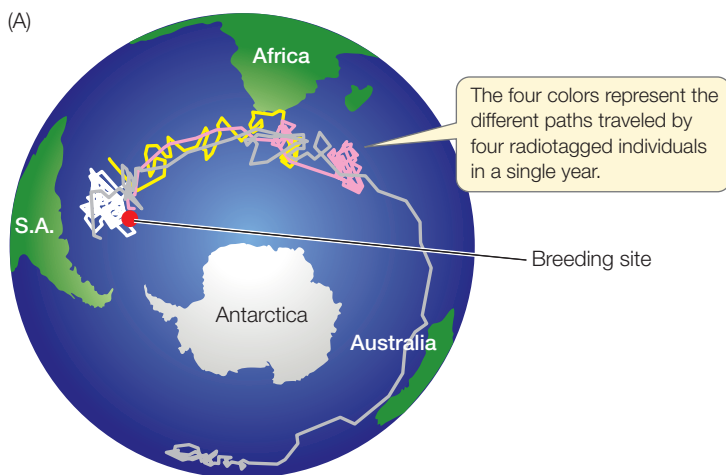

Many homing and migrating species are able to take direct routes to their destinations through environments they have never experienced because they use mechanisms of navigation other than piloting. Humans use two major forms of navigation:

- *Distance–direction navigation* requires knowing in what direction and how far away the destination is. With a compass to determine direction and a means of measuring distance, humans can navigate.
- *Bicoordinate navigation*, also known as *true navigation*, requires knowing the latitude and longitude (the map coordi-

nates) of both the current position and the destination, as well as a compass to determine direction.

Other animals, of course, do not carry compasses or GPS receivers, but many of them seem to have a *compass sense*, which allows them to use environmental cues to determine direction, and some appear to have a *map sense*, which allows them to determine their position.

The behavior of many animals suggests that they are capable of bicoordinate navigation. Gray-headed albatrosses, for example, breed on oceanic islands in the Southern Hemisphere. When a young gray-headed albatross first leaves its parents' nest, it flies widely over the southern oceans for 8 or 9 years before it reaches reproductive maturity (**Figure 53.17**). At that time, it flies back to the island where it was raised to select a mate and build a nest. How can it find a tiny island in an enormous ocean after years of wandering? A circadian clock probably gives the albatross information about the time of day and the additional information from the position of the sun might allow it to determine its map coordinates—much as sailors did in the days before global positioning satellites.

(B) *Thalassarche chrysostoma*

53.17 Coming Home (A) Gray-headed albatrosses are born on islands in the subantarctic oceans. Young birds roam widely over the southern oceans for 8 or 9 years. (B) Once they reach maturity, the birds return to the island where they were born to mate and raise their own young. A courting couple is shown here.

The ability to locate a position by calculating the angles between celestial objects such as the sun and stars and the horizon at specific times of day is called *celestial navigation*. During the day, the sun can serve as a compass for those species that can tell the time of day by means of their circadian clocks. This capacity has been demonstrated by “clock-shifting” experiments.

Researchers placed pigeons in a circular cage that enabled them to see the sun and sky, but no other visual cues. Food bins were arranged around the sides of the cage, and the birds were trained to expect food in the bin at one particular direction—south, for example. After training, no matter what time they were fed, and even if the cage was rotated between feedings, the birds always went to the bin at the southern end of the cage for food, even if that bin contained no food (**Figure 53.18**).

Next, the birds were placed in a room with a controlled light cycle in which the lights were turned on at midnight and off at noon. After 2 weeks of this treatment, the birds' circadian rhythms had been phase-advanced by 6 hours. Then the birds were returned to the circular cage under natural light conditions, with sunrise at 6:00 A.M. At sunrise, if the birds expected to find food in the south bin, then they should have looked for food 90 degrees to the right of the direction of the sun. But because their circadian clocks were telling them it was noon, they looked for food in the direction of the sun—in the east bin. The 6-hour shift in their circadian clocks resulted in a 90-degree error in their orientation, which showed that they were indeed using the sun as a compass. Similar experiments have shown that many animal species can orient by means of a *time-compensated solar compass*.

yourBioPortal.com

GO TO Animated Tutorial 53.4 • Time-Compensated Solar Compass

Many animals are normally nocturnal; in addition, many diurnal bird species migrate at night and thus cannot use the sun to determine direction. The stars offer two sources of information about direction: moving constellations and a fixed point. The positions of constellations (like that of the sun) change because Earth is rotating. With a star map and a clock, direction can be determined using any constellation. But one point that does not change position during the night is the point directly over the axis on which Earth turns. In the Northern Hemisphere, the star Polaris—the “North Star”—lies in that region of the sky and reliably indicates north.

Stephen Emlen at Cornell University showed that birds can learn to use the stars for orientation. As the time of year approaches when young birds would normally migrate to their winter range, young captive birds become more active and orient their activity in the direction they would fly. How do they know that direction? If these birds are raised in a planetarium with a natural star pattern, but one that does not rotate, the birds do not learn to orient, and their premigratory activity is random. However, if the planetarium sky rotates, and even if it rotates around a different point than the North Star, the birds orient their premigratory activity as if the fixed point in the sky was north.

INVESTIGATING LIFE

53.18 A Time-Compensated Solar Compass

Experiments show that pigeons use the sun to establish directions for navigation and finding food. “Clock-shifting” experiments demonstrate that the birds’ circadian clocks factor into their ability to judge direction correctly based on the sun’s position.

HYPOTHESIS Pigeons determine compass direction from the position of the sun with respect to their internal circadian clocks.

METHOD

1. Place a pigeon in a circular cage from which it can see the sun and sky, but not the horizon or any other visual cue.
2. Surround the cage with multiple food bins but place food only in the southernmost bin, thus training the bird to look for food in the south. (Rotating the cage but always placing the food in the southernmost bin confirms that the bird is navigating to find south.)

3. Place the trained pigeon in a room with a controlled light cycle for 2 weeks. Turn the lights on at midnight and off at noon to phase-advance its circadian rhythm by 6 hours (i.e., 6 A.M. feels like noon to the bird).
4. Return the pigeon to the circular cage under natural light and observe its food-seeking behavior.

RESULTS

A 6-hour shift in the circadian clock results in a 90-degree error in the pigeon's orientation.

CONCLUSION Pigeons have the ability to determine direction using the position of the sun as a compass.

Animals use multiple modalities to communicate

As individual animals interact, they exchange information; therefore, animal behavior can evolve into systems of information exchange, or **communication**. The behaviors of individuals may become elaborated into communication signals, but only if the transmission of information benefits both the sender and the receiver. To understand why these conditions must be met, consider male courtship displays such as that of the mallard shown in Figure 53.3. This display will be favored if it increases the sender's probability of mating and passing on his

genes, and sexual selection will occur if the display conveys information to a female (the receiver) about his qualities as a potential father for her offspring.

Animals communicate using a variety of sensory modalities that vary in the nature of the signal produced, the specificity of the information conveyed, the speed and persistence of the signal, and its suitability in different environments. Behavioral physiologists interested in communication must take into consideration the sensory and motor characteristics of their study animals as well as the physics of the communication

modalities they use and the environment in which the communication takes place.

CHEMICAL SIGNALS Because of the diversity of their molecular structures, pheromones can communicate very specific, information-rich messages (see Section 46.2). Pheromones are effective day and night, and they can cover a broad range of transmission distances. Pheromones used in different types of communication vary in their volatility (ease of vaporization) and diffusibility; these chemical properties are functions of the nature and size of the pheromone molecule. Pheromones that act as alarm signals, for example, are highly volatile and diffusible, so their message spreads rapidly, but disappears rapidly. Territory-marking and trail-marking pheromones have low volatilities and diffusibilities and stay effective for a long time, so they can convey directional information. Sex pheromones, such as that of the gypsy moth (see Figure 46.3), are intermediate in these properties, so they can spread a long distance, but do not disappear rapidly.

Pheromones are an effective way to exchange species-specific information, and because the recipient must have the proper receptor molecule to detect the pheromone, it is not a signal that is easily intercepted by predators. Pheromonal signals cannot be changed rapidly, but they can convey static, complex information. Mammals that mark their territories with pheromones reveal a great deal of information about themselves: species, individual identity, reproductive status, size (indicated by the height of the marking), and how recently the animal has been in the area (indicated by the strength of the scent).

VISUAL SIGNALS Visual signals offer the advantage of rapid delivery of information over considerable distances (depending on the environment and the visual acuity of the receiver); they also convey without ambiguity the position of the signaler. Signal content can be enhanced by movements (as in a courtship display) or by different postures. Effective visual signals, however, require sufficient light, and the receiver must be looking directly at the signaler. Thus, visual communication is not particularly useful at night or in environments that lack light, such as caves and ocean depths. Some species have overcome this constraint with light-emitting mechanisms. Fireflies, for example, use an enzymatic mechanism to create flashes of light. By emitting flashes in species-specific patterns, fireflies advertise for mates at night.

Another drawback of visual signals is that they can be intercepted by other species. There are predatory firefly species, for example, that mimic the flash pattern of females of other species. A male that approaches the mimicking “female,” becomes a meal rather than a mate. Thus deception can be part of animal communication systems, just as it is part of human communication.

ACOUSTIC SIGNALS Sound cannot convey complex information as rapidly as visual signals can. But acoustic signals, unlike visual signals, can be used at night and in dark environments. They are not hindered by objects that would interfere with visual signals, so they can be transmitted in complex environments such as forests. They are often better than visual signals

at getting the attention of a receiver because the receiver does not have to be looking at the signaler for the message to be received. Sounds are also useful for communicating over long distances. Even though the intensity of a sound decreases with distance from the source, loud sounds can transmit information over much longer distances than visual signals can. The complex songs of humpback whales, for example, when produced at ocean depths of about 1,000 meters, can be heard hundreds of kilometers away. In this way, humpback whales can locate one another across vast expanses of ocean.

The information content of acoustic signals can be increased by varying their frequency, as we can see in the sonograms of the species-specific songs of birds shown in Figure 53.9, and as we practice in our own speech. However, acoustic signals place the signaler at risk for detection by predators. This danger can be minimized by adjustments of frequency and signal structure that decrease the directional information the receiver can extract from the signal. Alarm calls tend to be pure tones (a single frequency) without much temporal structure (starts and stops). It is very difficult to localize such calls. On the other hand, territorial calls tend to cover a broad frequency range and have temporal structure. These calls are easy to localize. The frequencies and structures of acoustic signals are also adapted to specific habitats. Different vegetation types, for example, have different sound-absorbing properties: pure tones at lower frequencies carry better in forests, and more complex calls at higher frequencies carry well in open habitats.

MECHANOSENSORY SIGNALS Animals in close contact with one another communicate by touch, especially under conditions in which visual communication is difficult. The best-studied use of mechanosensory communication is the dance of honey bees, first described by Karl von Frisch. Honey bees have a spectacular ability to navigate and can reliably communicate the location of food sources as far as 2.5 km away from their hive. When a forager bee finds food, she returns to the hive and communicates her discovery to her hive-mates by dancing in the dark hive on the vertical surface of the honeycomb. Other bees follow the dancer and receive her message.

If the food source is more than about 100 m away from the hive, the forager performs a *waggle dance* (Figure 53.19), which conveys information about both the distance and the direction of the food source. She repeatedly traces out a figure-eight pattern as she runs on the honeycomb. She alternates half-circles to the left and right with vigorous wagging of her abdomen in the short, straight run between turns. Bees use the sun as their compass, and the angle of the straight run indicates the direction of the food source relative to the position of the sun projected down to the horizon. Even under cloudy conditions, the forager can provide directions to the food source because she can see polarized light. The honey bee’s internal clock allows the dancer to adjust her dance to take into account the sun’s movement during her return flight. The speed of the dance indicates the distance to the food source: the farther away it is, the longer the duration of each waggle run.

If the food she has found is less than 80 m from the hive, the forager performs a *round dance*, running rapidly in a circle and

53.19 The Waggle Dance of the Honey Bee (A) A honey bee runs straight up on the vertical surface of the honeycomb in the dark hive while wagging her abdomen to tell her hivemates that there is a food source in the direction of the sun. (B) When her waggle runs are at an angle from the vertical, the other bees know that the same angle separates the direction of the food source from the direction of the sun.

GO TO Web Activity 53.1 • Honey Bee Dance Communication

reversing her direction after each full circle. The odor on her body and the round dance combine tactile and chemical cues: the odor indicates the flower to be looked for, and the dance communicates the fact that the food source is close to the hive.

COMMUNICATION IN MULTIPLE SENSORY MODALITIES Avoiding ambiguity is a high priority in any signaling system. Signal specificity is enhanced if multiple sensory modalities are used. Courtship behavior in fruit flies, for example, involves tactile, chemical, visual, and acoustic signals (see Figure 53.6A). The male fruit fly orients toward the female and taps her body with his foreleg (touch). Upon detection of pheromones in her cuticle (chemical), the male begins to vibrate one wing, producing a species-specific “courtship song” (acoustic). The male then extends his mouthparts to taste the female’s genitalia (chemical and tactile); if she is receptive, he initiates copulation. At any point, if any sensory feedback indicates to either the male or the female that their pairing is inappropriate, the courtship abruptly ends.

53.5 RECAP

Biological rhythms allow an animal to anticipate changes in its environment. In mammals, a circadian clock located in the suprachiasmatic nuclei generates a rhythm that is entrainable by environmental information. The navigational abilities of animals range from simple piloting by landmarks to distance-and-direction and bicoordinate navigation. Behaviors may evolve into communication signals if the transmission of information benefits both the sender and the receiver.

- What is meant by a “free-running” rhythm? Describe how it can be entrained to the 24-hour day. **See pp. 1127–1128 and Figure 53.15**
- Explain the difference between piloting, distance-and-direction navigation, and bicoordinate navigation. **See pp. 1129–1130**
- Give an advantage and a disadvantage for each of three modalities of communication. **See pp. 1131–1133**

We have just seen how a behavioral physiologist might look at the courtship behavior of a male fruit fly. A behavioral ecologist would probably approach this behavior in a different way, asking how it influences the fitness of both the male fly and his mate. Given that interactions between individual animals, especially those involved in mating and the care of offspring, are so directly tied to fitness, it is not surprising that they are an important focus of behavioral studies.

53.6 How Does Social Behavior Evolve?

The evolution of social behavior became a field of study in its own right in 1975, with the publication of E. O. Wilson’s landmark book, *Sociobiology*. We begin our consideration of this enormous field with simple interactions that involve a single male and a single female, but already we see diversity. Species differ in their mating systems, which vary from monogamous to promiscuous; in the amount of parental care they give their young; and in the degree to which the male contributes to raising the young. Beyond these relatively simple mating systems, there are associations of larger numbers of reproductive individuals in *polygynous* mating systems, in which a male has more than one mate, or *polyandrous* mating systems, in which a female has more than one mate. Even more complex interactions exist in which extended families participate in raising young, and finally there are societies such as honey bee colonies in which large numbers of nonreproductive individuals assist a single reproductive individual. Sociobiology proposes that the evolution of all these variations can be understood by asking how social behavior contributes to the fitness of the *individuals* involved.

Mating systems maximize the fitness of both partners

At the start of Chapter 7, we learned about the mating behavior of two species of voles. Prairie voles (*Microtus ochrogaster*) are *monogamous*, forming strong pair bonds that can last for life, and both parents participate in rearing the young. In contrast, montane voles (*M. montanus*) are *promiscuous*: males mate with many females, and the young are raised by the females alone. Behavioral physiologists have explained the proximate mechanisms behind these stark behavioral differences in terms of the release of neurohormones and the distribution of the receptors for those hormones in the brains of the two species. The ultimate question—and the one asked here—is why two such different mating systems evolved in two species that are so closely related.

We begin with the premise that there is an asymmetry in the contributions of male and female animals to their offspring at the time of fertilization. As we learned in Section 44.1, females produce a limited number of eggs, and each egg is generously stocked with resources. Males produce an almost infinite number of sperm, which contain next to no resources. So the energetic and opportunity costs of reproduction are greater for the female than for the male. In mammals, this asymmetry increases throughout gestation as the female bears most of the costs. By the time of birth or hatching, the female's investment in the young is much greater than the male's investment, and the main way for the female to maximize her fitness is to make sure her young are healthy and survive to pass on her genes.

The male has different options for maximizing his fitness. He can simply move on after inseminating the female and seek additional mates as a means of maximizing his reproductive success—as in the case of the meadow vole. Or he can stay with the female he inseminated, protect her, and help care for their young—as in the case of the prairie vole. Which strategy maximizes his fitness depends on a number of factors that are influenced by the species' environment, such as the likelihood that a female and her offspring will survive without a male's help, and a male's likelihood of finding another fertile female. Thus sociobiologists seek to quantify these factors in nature as a means of explaining observed differences in mating systems.

POLYGyny **Polygynous** mating systems, in which a male has more than one mate, involve a different asymmetry. In situations in which a male can sequester a group of females from other males, he can increase his fitness by increasing the number of females in his group. As we saw in Section 53.4, male elephant seals accomplish this by protecting an area of beach where females give birth. Male baboons do so by herding females. Male red-winged blackbirds may acquire more than one mate by defending high-quality nesting territories, building more than one nest in their territories, and attracting females to those nests. Since sex ratios in all these species are close to 50-50, a large differential in male fitness is established: some males have high reproductive success while many males have none. Thus selection favors males that are successful in competing with other males to obtain and protect access to many females. In general, bigger, stronger males are the winners, and sexual dimorphism in body size evolves. The elephant seal is an extreme example:

males may weigh more than three times as much as females. When species with polygynous mating systems are compared, there is a strong correlation between the number of females a male controls and the degree of sexual dimorphism.

Why do females participate in these polygynous mating systems? Why doesn't a female seek out a nice, kind, noncompetitive male? In some cases she has no choice. If a female elephant seal wants to have her pup on a safe beach, she must enter the territory of a male. If a female red-winged blackbird wants to nest in an optimal territory, she will have to share the attentions of the territory's owner with other females. However, even if the female has a choice of mates, she is likely to maximize her fitness by mating with a male who is strong and dominant enough to control a number of females. Why? If her mate is a dominant male, her male offspring are likely to have their father's traits, become dominant males, and give her more grandchildren. The ultimate result of females selecting males for their prowess and dominance in male-male competition is the lek mating system (see Figure 53.12C), in which the *only* thing a male offers a female is the display of his dominance over other males.

POLYANDRY A mating system in which one female mates with multiple males is called **polyandry**. This type of mating system is relatively rare, but it is seen in some birds and a few mammal species in which paternal care for the young can have a large effect on fitness. That is the case the golden lion tamarins (*Leontopithecus rosalia*), primates native to the Brazilian tropical forests (**Figure 53.20**). In comparison to other primates, tamarins are tiny—under 1 kg—so they face high predation pressure. Females usually give birth to twins and thus newborns constitute a higher percentage of maternal weight than those of other primates. They also grow faster, so nursing costs are high. For all these reasons, young tamarins cared for by their mother alone are unlikely to survive.

Leontopithecus rosalia

53.20 Polyandry in a Small Primate The endangered golden lion tamarins of Brazil are small primates whose unique life history has given rise to polyandry in some groups, with males playing a major role in rearing the young.

What can a male tamarin do to help guarantee his reproductive success? Watching out for predators is one obvious contribution; gathering food for the female and her young is another. Like other primate parents, tamarins carry their young most of the time, but most other primates have single offspring. When tamarin mothers are carrying twins, they spend 92 percent of the time resting, in comparison to only 58 percent of the time when they are not carrying young. Resting is not compatible with foraging and filling the mother's high energy requirements. When a male is present, however, he carries the young about one-third of the time, so the mother has much more time for foraging and feeding.

If one male is helpful in protecting and raising young, then two should be even more helpful. Some females can attract a second mate by being sexually receptive to him. Neither male can be sure that any eventual offspring are his, so it is in the best interest of both to help in their rearing. Of the social groups observed in field studies, only 22 percent had one male and one female, whereas 61 percent had multiple males and one female.

Fitness can include more than producing offspring

As humans, we readily understand the concept of extended family—brothers, sisters, aunts, uncles, nieces, nephews. Extended families are a common form of social organization in other species as well, and members of these families may cooperate in territory defense, predator avoidance, foraging, and rearing of young. If behavior is favored when it increases the fitness of the individual performing it, then how can we explain the evolution of social behaviors that do not lead to the performer having more offspring and may even appear to be **altruistic**—benefiting another individual at a cost to the performer?

An individual's fitness is increased by having offspring because those offspring carry the parent's genes into the next generation. Fitness gained by producing offspring is referred to as **individual fitness**. However, an individual's genes are carried into the next generation by more than his or her own offspring. In diploid organisms, two offspring of the same parents share, on average, 50 percent of the same alleles, and an individual is

likely to share 25 percent of its alleles with its sibling's offspring. Therefore, by helping parents and other relatives raise their offspring, an individual increases the transmission of those shared alleles to the next generation. **Inclusive fitness** is the fitness derived from an individual's own reproductive success plus that derived through the reproductive success of its relatives.

The maximization of inclusive fitness is the mechanism behind **kin selection**: selection for behaviors that increase the reproductive success of relatives even when they come at a cost to the performer. An example is the phenomenon of *helping at the nest*, which was extensively studied in Florida scrub jays by Glen Woolfenden. Scrub jay pairs mate for life and establish large territories, which they defend aggressively. The mating pair may be assisted in rearing their young by 3 to 5 helpers (**Figure 53.21**). The helpers guard against predators, feed the young, clean the nest, and fly with fledglings. Why are these birds helping others rather than rearing their own young? Through a long-term study, Woolfenden was able to establish a number of important facts:

- The helpers are prior offspring of the mating pair and are usually 1 to 3 years old.
- Young birds that attempt to breed have almost zero reproductive success.
- Mating pairs with helpers have approximately 3 times the reproductive success of those without helpers.

These results support the conclusion that helper scrub jays are maximizing their inclusive fitness by helping their parents raise siblings until they are old and mature enough to have a reasonable probability of successfully raising their own offspring.

The concept of kin selection was formalized by W. D. Hamilton in what has become known as **Hamilton's rule**. He argued that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness between the performer and the recipient had to be greater than the cost to the performer. This relationship was clearly stated years before by the eminent geneticist J. B. S. Haldane, who said during an argument about altruism that he would not be willing to risk his life to save his brother—but for 2 brothers or 8 cousins, he would consider it.

53.21 Helpers at the Nest

Young Florida scrub jays (*Aphelocoma coerulescens*) often forego reproduction in their first few years of adulthood to help their parents raise their siblings. These young birds help their parents feed the nestlings, defend the territory, and protect the nest from predators.

Eusociality is the extreme result of kin selection

Species such as honey bees whose social groups include nonreproductive workers are called **eusocial** species. Prime examples are wasps, bees, and ants—members of the large insect order *Hymenoptera*. In a honey bee colony, the single reproductive female—the queen—occasionally produces a few male offspring, but most of the thousands of other individuals in the colony—her offspring—are sterile female workers. The key to understanding the evolution of eusociality in hymenopterans is their sex determination mechanism, called **haplodiploidy** because diploid individuals are female and haploid individuals are male. The queen carries a lifetime supply of sperm obtained during her single mating flight, and she controls whether her eggs are fertilized or not. An unfertilized egg develops into a male, a fertilized egg develops into a female.

If a queen copulates with only one male, all the sperm she receives are identical because a haploid male has only one set of chromosomes, all of which are transmitted to every sperm cell. Therefore, the queen's daughters share all of their father's genes and, on average, half of their mother's genes. As a result, the workers in the hive—all sisters—share, on average, 75 percent of their alleles. Were they to reproduce, they would share only 50 percent of their alleles with their own female offspring. Thus they can potentially increase their inclusive fitness more by caring for their sisters than by producing and caring for their own offspring.

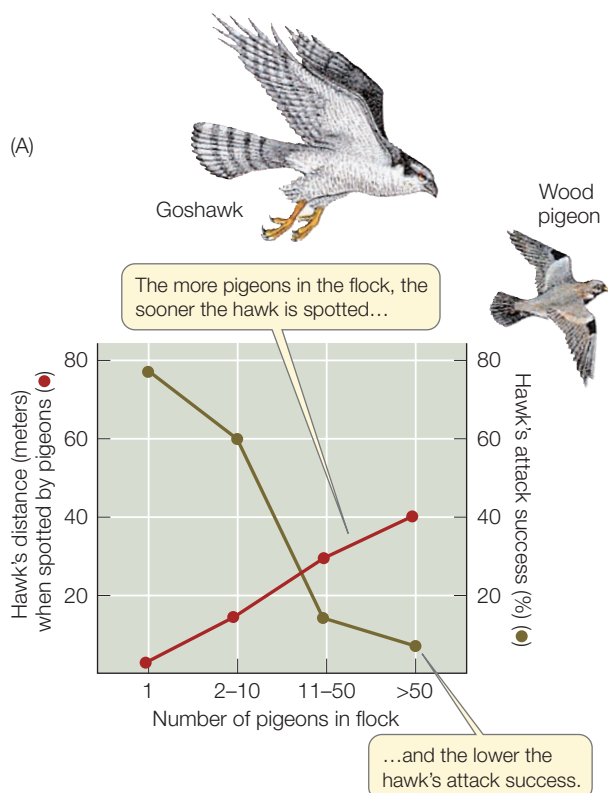

Haplodiploidy is not essential for eusociality to evolve. This social system may also arise if it is costly or dangerous to establish new colonies. Nearly all eusocial animals construct elaborate nests or burrow systems within which their offspring are reared. Such a structure represents an enormous investment of resources. Naked mole-rats—the most eusocial mammals—live

Heterocephalus glaber

53.22 A Eusocial Mammal Naked mole-rats live in a large colony with only one reproductive female and a few reproductive males. They live in an elaborate tunnel system excavated by the colony over time.

in elaborate underground tunnel systems that can extend for as much as 5 kilometers in cumulative length (**Figure 53.22**). A colony includes 70 to 80 individuals but only one reproductive female and a few reproductive males. The other colony members are sterile workers that dig and maintain the tunnels, guard against intruders, harvest food (tubers), and use their feces to feed the queen and her offspring. Individuals attempting to found new colonies have a high risk of failing or being captured by predators. When chances of individual reproductive success are practically zero, an individual can best maximize its inclusive fitness by staying with and helping to maintaining the colony.

(B) *Spermophilus beldingi*

53.23 Group Living Provides Protection from Predators

Animals that live in groups can spread the cost of looking out for predators. (A) The larger the number of pigeons in a flock, the greater the chances that one of the pigeons will spot a hawk before it attacks, and the lower the chances that the hawk will capture one of the pigeons. (B) A young male Belding's ground squirrel gives an alarm call upon spotting a predator. Although this behavior increases his individual risk of becoming its prey, he increases the survival chances of many of his close relatives.

Group living has benefits and costs

Apart from their direct influences on reproductive success, social systems can contribute to survival in many ways, but they can also involve costs. Thus the cost–benefit approach of behavioral ecology is relevant to understanding the evolution of social behavior.

An obvious example of a benefit of group living is improved foraging efficiency. By hunting in packs, African wild dogs (see Figure 59.17) employ cooperative strategies that enable them to bring down larger prey than could a single dog. The larger the pack, the greater the hunting success rate. Once the prey is killed, the presence of conspecifics also reduces the risk that the wild dogs will lose their prey to larger scavengers, such as hyenas.

Living in a group can also reduce the risk of the members' becoming prey themselves. Many small birds forage in flocks. To test the hypothesis that flocking provides protection against predators, one investigator released a trained goshawk near wild wood pigeons in England. The hawk was most successful when it attacked solitary pigeons. Its success in capturing a pigeon in a flock decreased as the number of pigeons in the flock increased (Figure 53.23A). The larger the flock, the sooner some individual in the flock spotted the hawk and flew away. This escape behavior stimulated other individuals in the flock to take flight as well.

Alarm calling is another means of reducing predation risk, but the caller incurs a risk cost by calling attention to itself. Belding's ground squirrels live in large colonies in open meadows. When one squirrel announces the presence of a predator with loud, sharp barks, all the nearby squirrels dive into their burrows (Figure 53.23B). Paul Sherman showed that callers double their risk of being preyed on—so why do they do it? Sherman's and others' research has shown that this altruistic behavior is a product of kin selection. In this polygynous species, males establish large territories in the spring that include the territories of several females, whom they inseminate. The females then drive the males off. Female offspring settle near their mothers, so neighboring females in a colony tend to be sisters, and they defend each other's young. Sherman showed that males are less likely to give alarm calls than females, and that females are more likely to give alarm calls when related individuals are nearby.

Social behavior has many costs as well as benefits. Foraging in a group may reduce the amount of food available to each individual, and the foraging individuals may interfere with one another's foraging activities. Individuals living in groups may face more competition for mates, as well as for food, than solitary individuals would. A large group may actually attract the attention of predators. And living at high population densities can increase the risk of disease transmission. The study of disease transmission in wild animal populations is a relatively new field, but such studies have made it apparent that species living in social groups are more prone to outbreaks of disease than are solitary species.

53.6 RECAP

Social behavior can be understood by asking how it contributes to the fitness of the individuals involved. Asymmetry between the sexes in parental investment is a key factor in the evolution of mating systems. According to the theory of kin selection, an individual can increase its fitness by helping related individuals with whom it shares alleles. In extreme cases, kin selection has given rise to eusociality.

- What environmental conditions can lead to monogamy, polygamy, or polyandry? **See pp. 1134–1135**
- Explain how an individual can increase its fitness by helping its relatives. **See p. 1135**
- Why is eusociality so common among hymenopterans? **See p. 1136**
- What are some of the costs and benefits of group living? **See p. 1137 and Figure 53.23**

Knowledge of the behavior of particular species—how they use the environment, how they obtain food, how they organize their activities spatially and temporally—is essential for understanding how species interact in nature. These interactions are one focus of the science of ecology, the subject of Part Ten of this book.

CHAPTER SUMMARY

53.1 What Are the Origins of Behavioral Biology?

- Ivan Pavlov's discovery of **conditioned reflexes** and B. F. Skinner's research on **operant conditioning** as a model for learning led to an approach called **behaviorism** that mainly carried out laboratory experiments on rats and a few other animal models. **Review Figure 53.1**
- **Ethology** focuses on both the **proximate causes** of behavior—what is the immediate cause of the behavior, and how does the behavior develop?—and on the **ultimate causes**—how does the behavior affect the animal's fitness, and how does it compare with similar behaviors in related species?

- A major focus of the ethologists was **fixed action patterns** and their **releasers**. They performed **deprivation experiments** as well as breeding experiments to demonstrate that certain behaviors are genetically determined.

53.2 How Can Genes Influence Behavior?

- Breeding experiments can reveal whether a behavioral phenotype is inherited. Gene knockout experiments can reveal the roles of specific genes underlying a behavioral phenotype. **Review Figures 53.4 and 53.5**
- Most behaviors are complex traits involving many genes that function in cascades and offer many points for a change in a single gene to influence behavior. **Review Figure 53.6**

53.3 How Does Behavior Develop?

- Hormones can determine the pattern of behavior that develops and the timing of its expression. **Review Figure 53.7**
- **Imprinting** is a process by which an animal learns a specific set of stimuli during a limited **critical** or **sensitive period**. That critical period may be determined by hormones.
- The development and expression of song in white-crowned sparrows involves a genetic predisposition to learn the species-specific song, a critical period for imprinting of a song memory, and hormonally controlled timing of song expression. Social interactions may also play a role. **Review Figure 53.9**

53.4 How Does Behavior Evolve?

- An animal's behavior is a series of choices that influence its fitness. To make these choices, animals use environmental cues that are reliable predictors of the potential effects of their choices on their fitness. **Review Figure 53.10**
- The **cost-benefit approach** can be used to investigate the fitness value of specific behaviors. The cost of a behavior typically has three components: **energetic cost**, **risk cost**, and **opportunity cost**. **Review Figure 53.11, ANIMATED TUTORIAL 53.1**
- According to **optimal foraging theory**, animals should practice feeding behaviors that maximize their energetic gain at the least cost. **Review Figure 53.13, ANIMATED TUTORIAL 53.2**

53.5 What Physiological Mechanisms Underlie Behavior?

- **Circadian rhythms** control the daily cycle of behavior. Without environmental time cues, circadian rhythms free-run with a period that is genetically programmed. They are normally **entrained** to the light-dark cycle by environmental cues. **Review Figure 53.15, ANIMATED TUTORIAL 53.3**
- **Circannual rhythms** are endogenous yearly cycles whose neural basis is still unknown.
- Three forms of navigation used by animals to find their way in the environment are piloting (orienting to landmarks), distance-direction navigation, and bicoordinate navigation. Navigation mechanisms include celestial navigation and a time-compensated solar compass. **Review Figures 53.16–53.18, ANIMATED TUTORIAL 53.4**

- The behaviors of individuals may become communication signals if the transmission of information benefits both the sender and the receiver.
- Chemical communication signals (pheromones) can be highly specific and have different time courses depending on their volatility and diffusibility. Visual signals can convey complex messages rapidly, but the recipient must be looking at the sender. Acoustic signals travel well over distances, do not require a focused recipient, and can be modified to reveal or conceal directional information. Tactile signals are used by animals in close proximity and can convey complex messages. **Review Figure 53.19, WEB ACTIVITY 53.1**

53.6 How Does Social Behavior Evolve?

- The evolution of mating systems can be understood by looking at the fitness costs and benefits incurred by each partner in the species' environment. **Polygynous** mating systems, in which one male controls and mates with many females, can result in great variation in male reproductive success. **Polyandry**—a female mating with multiple males—can evolve in circumstances in which a male can make a substantial contribution to the survival of his offspring.
- The fitness an individual gains by producing offspring (**individual fitness**) plus the fitness it gains by increasing the reproductive success of relatives with whom it shares alleles is called **inclusive fitness**. **Kin selection** may favor **altruistic** behavior toward relatives, despite its cost to the performer, if it increases the performer's inclusive fitness.
- As a result of **haplodiploidy**, the sex determination mechanism of the Hymenoptera, nonreproductive workers share more alleles with one another than females share with their own offspring. Haplodiploidy has probably facilitated the evolution of **eusociality** in this group through kin selection. Eusociality has also risen in diploid species in which chances of individual reproductive success are extremely low.
- Group living confers benefits such as greater foraging efficiency, protection from predators, but it also has costs, such as increased competition for food and ease of transmission of diseases.

SEE WEB ACTIVITY 53.2 for a concept review of this chapter.

SELF-QUIZ

- Which of the following is *not* true of a fixed action pattern?
 - Its expression may depend on hormonal conditions.
 - It is induced by complex, species-specific stimuli.
 - It is highly stereotypic and species-specific.
 - It can be expressed even if the animal has never seen it performed.
 - Its genetic basis can be demonstrated by breeding experiments.
- Which of the following is *not* a component of the cost of performing a behavior?
 - Its energetic cost
 - The risk of being injured
 - Its opportunity cost
 - The risk of being attacked by a predator
 - Its information cost
- Birds that migrate at night
 - inherit a star map.
 - determine direction by knowing the time and the position of a constellation in the sky.
 - orient to a particular point in the sky.
 - imprint on one or more key constellations.
 - determine distance, but not direction, from the stars.
- If a bird is trained to seek food on the western side of a cage open to the sky, and is then placed in a chamber with a controlled light cycle so that its circadian rhythm becomes phase-delayed by 6 hours (i.e., its circadian rhythm is 6 hours behind real time), when it is returned to the open cage at noon in real time, it will seek food in the
 - north.
 - south.
 - east.
 - west.
- To be able to pilot, an animal must
 - have a time-compensated solar compass.
 - orient to a fixed point in the night sky.
 - know the distance between two points.
 - know landmarks.
 - know its longitude and latitude.

6. Which of the following statements about communication is *true*?
 - a. Complex information cannot be conveyed by pheromones.
 - b. Visual signaling is advantageous in complex environments.
 - c. Acoustic communication always reveals the location of the signaler.
 - d. An advantage of pheromones is that the message can persist over time.
 - e. The dance of honey bees is an example of visual signaling.
7. A cost commonly associated with group living is
 - a. increased risk of predation.
 - b. interference with foraging.
 - c. higher exposure to diseases and parasites.
 - d. poorer access to mates.
 - e. All of the above
8. The choice of a mating partner may be based on
 - a. the competitive ability of a potential mate.
 - b. the territory held by a potential mate.
 - c. both the competitive ability of a potential mate and the territory it holds.
 - d. the courtship display of a potential mate.
 - e. all of the above
9. Altruistic behavior
 - a. can increase an individual's inclusive fitness.
 - b. depends on haplodiploid sex determination.
 - c. is most common between unrelated individuals.
 - d. always causes a net decrease in the performer's fitness.
 - e. characterizes a monogamous mating system.
10. A social group is said to be eusocial if
 - a. group members interact very intensively.
 - b. some group members produce many more offspring than others do.
 - c. a dominance hierarchy exists among group members.
 - d. young individuals remain in the group to help their parents rear other offspring.
 - e. the group contains nonreproductive helper individuals.

FOR DISCUSSION

1. Cowbirds are nest parasites. A female cowbird lays an egg in the nest of another bird species, which then incubates the egg and raises the chick. What do you think would characterize the acquisition of song in cowbirds? In a given area, cowbirds tend to parasitize the nests of particular bird species. How do you think female cowbirds learn this behavior? How would you test your hypothesis?
2. Male dogs lift a hind leg when they urinate; female dogs squat. If a male puppy receives an injection of estrogen when it is a newborn, it will never lift its leg to urinate for the rest of its life; it will always squat. How might this result be explained?
3. The short-tailed shearwater is a bird that winters in Antarctica and summers in the Arctic. What problems would this species have in using either the sun or the stars for navigation? What is the most likely means it uses to find its way to its summer and its winter feeding grounds?
4. In most vertebrate species with helpers, the helpers are individuals capable of reproducing, and most of them later breed on their own. Among eusocial insects, sterile castes have evolved repeatedly. What differences between vertebrates and insects might explain the failure of sterile castes to evolve in the former?

ADDITIONAL INVESTIGATION

Experiments on animal migration show that animals can use a time-compensated solar compass or identification of a fixed point in the night sky as a basis for distance-and-direction navigation. However, the observations on the homing ability of seabirds such as the albatross indicate that animals might be capable of true or bicoordinate navigation. What experiments could you do to

prove that animals have that capability, and what experiments could you do to test hypotheses about the mechanisms they might use? (*Hint:* At least two hypotheses might involve using the elevation of the sun or the angles of Earth's magnetic lines of force as a means of determining latitude.)

WORKING WITH DATA (GO TO yourBioPortal.com)

The Costs and Benefits of Foraging Behavior In this exercise based on Figure 53.13, you will analyze the techniques and results of Werner and Hall's experiments with bluegill sunfish

and answer questions pertaining to experiments such as this one that seek to quantify behaviors.

Dung happens

In 1788, eleven ships carrying settlers from Great Britain landed on the shores of Australia (then called New South Wales), laden with all the supplies the settlers anticipated would be needed to found a new European colony on that continent. The arriving cargo included two bulls and five cows, which would provide the foundation of an important livestock industry. The settlers, however, made a grievous error by failing to bring along dung beetles.

Dung beetles are beetle species that during their larval life consume the dung, or excrement, of vertebrates, primarily grazing mammals. Some species lay eggs directly into the dung pat where it was deposited; others carve up the dung pat and form the pieces into balls, which are then rolled away and buried. Australia's native dung beetles, accustomed to processing and burying the dry, fibrous dung pats of kangaroos, wombats, and other indigenous marsupial mammals, were unable to handle

the copious quantities of wet manure produced by the rapidly expanding numbers of cattle and sheep.

A cow can drop 10 to 12 dung pats every day and, in the absence of dung beetles to break up and bury the dung, thousands of acres of Australian pasture were rendered unusable for grazing livestock.

In addition, the cattle dung proved an exceptionally suitable habitat for the larvae of the bush fly, *Musca vetustissima*, so fly populations exploded. The flies became so pestiferous, flying into people's faces, that eating, drinking, and even breathing were rendered nearly impossible in some parts of Australia at certain times of year.

In 1964, Australia's national science organization tackled the dung problem. Entomologists traveled to Africa and other parts of the world to find dung beetle species that could process and bury cattle dung. The first such species, *Onthophagus gazella*, was imported from South Africa in 1968. Four more species arrived the next year,

and by 1984, over 50 dung beetle species from around the world had been brought to Australia to take up the task of cattle dung cleanup.

Multiple species with different habitat and climate requirements were needed to cover the different environments across the Australian continent. The project, deemed a resounding success, not only reduced bush

Onthophagus gazella in Australia Dung beetles from Africa are capable of processing the moist manure of introduced mammals such as cattle.

Freed from Bush Flies The importation of dung beetles essentially saved the livestock industries of Australia from plagues of bush flies breeding in the moist dung of cattle and other imported mammals.

fly populations, but had other desirable effects. The beetles reduced the incidence of parasitic infections in cattle by roundworms, hookworms, and other dung-breeding worms, and they increased pastureland productivity by releasing nitrogen from the dung into the soil.

The passengers and crew of the ships that brought cattle to Australia had no idea that they were carrying out a massive ecological experiment. By intent or by accident, people have been moving all kinds of organisms from their native habitats to places they have never lived before. It is now abundantly clear that introducing organisms into existing communities can have unanticipated repercussions and that even small organisms can have large effects on energy flow and nutrient cycling in ecosystems.

IN THIS CHAPTER we will introduce and define the field of ecology. We will see how the physical features of the environment, including climate and geological history, influence the distribution and abundance of organisms. Next we will introduce and describe the major biomes, biogeographic regions, and aquatic environments across which Earth's organisms are distributed.

CHAPTER OUTLINE

- 54.1 What Is Ecology?
- 54.2 Why Do Climates Vary Geographically?
- 54.3 What Is a Biome?
- 54.4 What Is a Biogeographic Region?
- 54.5 How Is Life Distributed in Aquatic Environments?

54.1 What Is Ecology?

Ecology is the scientific investigation of interactions among organisms and between organisms and their physical environment. Ecology is a relatively new branch of the biological sciences; in fact, it did not even have a formal name until 1866. Like evolutionary biology, ecology owes its existence to Charles Darwin, who described the focus of *The Origin of Species* as “the coadaptation of organic beings to each other and to their physical conditions of life.” Ernst Haeckel, a German biologist who was profoundly influenced by Darwin, constructed a new word for this new enterprise: *ecology*, from the Greek root *oikos*, “house,” where “house” embraces all of an organism’s environment. As Haeckel explained, “Ecology is the study of all those complex interrelations referred to by Darwin as ‘the conditions of the struggle for existence.’”

Ecology provides explanations of the perceptible, palpable world. Although the *consequences* of enzyme–substrate interactions can be visible, the reactions themselves are not readily visible to the casual observer. In contrast, interactions among organisms, and between organisms and their environment, can, with persistence and ingenuity, be observed. Analysis of those observations, however, often requires additional investigation. That butterflies visit flowers has been observed, and admired aesthetically, for centuries; that butterflies perform a useful service to the flowers they visit by transporting pollen is an ecological insight less than 250 years old.

The need for sound science in making decisions about our own interactions with the environment is another important reason for studying ecology. Humans are part of the biotic environment of a tremendous variety of organisms, and our activities have profound effects on energy flow and nutrient cycling through the physical environment. Ecologists can provide objective data on the consequences of human activities. An understanding of ecology greatly improves our ability to grow food sustainably; to manage pests and diseases safely and effectively; and to deal with natural disasters such as floods and fires. The greater our understanding of ecological interactions, the greater the likelihood that we can accomplish these things without causing a cascade of unanticipated consequences for ourselves and other organisms.

Ecology is not the same as environmentalism

In defining what ecology is, it is important to emphasize what ecology is *not*. “Ecology” is sometimes equated with “environmentalism,” but the two terms are not equivalent. Ecology is a science that generates knowledge about interactions in the nat-

ural world; as a field of inquiry, it is not inherently focused on human concerns. **Environmentalism** is the use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy relating to stewardship of natural resources and ecosystems.

Ecologists study biotic and abiotic components of ecosystems

From its beginnings, ecology has encompassed both the living, or **biotic**, components and the **abiotic**, or physical and chemical, components of the environment. But the field has advanced and diversified considerably since Haeckel's time. A continuous influx of new tools—mathematical models, molecular techniques, and satellite imaging, to name just a few—as well as new connections to other fields, particularly the physical sciences—have dramatically changed ecological research. Its ultimate goal, however, remains the same: to identify and understand the biotic and abiotic forces that influence the distribution and abundance of organisms.

54.1 RECAP

Ecology is the scientific investigation of interactions among organisms and between organisms and their physical environment.

- What are some reasons to consider ecology a useful scientific enterprise? **See p. 1141**
- How does ecology differ from environmentalism? **See pp. 1142–1143**

Climate is one of the abiotic factors that determine the kinds of organisms that can survive and reproduce in a particular place. Because climates set limits on the distribution and abundance of organisms, understanding Earth's climates is a good place to begin our study of ecology.

54.2 Why Do Climates Vary Geographically?

The terms *weather* and *climate* both refer to atmospheric conditions—temperature, humidity, precipitation, wind direction and velocity—but they refer to different time scales. **Weather** is the short-term state of atmospheric conditions at a particular place and time, whereas **climate** refers to the average atmospheric conditions, and the extent of their variation, at a particular place over a longer time. In other words, climate is what you expect; weather is what you get. The responses of organisms to weather are usually short-term—seeking shelter from a sudden rainstorm, for example, or shivering to keep warm when the temperature drops. Responses to climate, on the other hand, tend to be adaptations that affect physiology, morphology, and behavior.

These adaptations are among the forces driving speciation over evolutionary time.

Global climates are solar powered

Solar energy input, which determines air temperature, is the major determinant of climates on Earth. The intensity of solar radiation varies from place to place due to the shape of Earth and the tilt of its axis, and its orbit around the sun. The amount of solar energy reaching a given unit of Earth's surface depends primarily on the angle of the sun's rays (**Figure 54.1**). At high latitudes (areas close to the poles), sunlight strikes Earth's surface at an angle, so the incoming solar energy is distributed over a larger area (and is thus less intense) than at the Equator, where sunlight strikes Earth's surface perpendicularly. Moreover, when coming in at an angle, the sun's rays must pass through more of Earth's atmosphere, so more of their energy is absorbed and reflected before it reaches the ground. Because of this difference in solar energy input, air at the poles is colder than air at the Equator. The average temperature of the air over the course of the year decreases about 0.4°C for every degree of latitude (about 110 km) at sea level. In addition, because of the tilt of Earth's axis relative to the sun, higher latitudes experience greater variation in both day length and the angle of arriving solar energy over the course of a year, leading to more seasonal variation in temperature.

In the atmosphere closest to Earth's surface, air temperatures also decrease with elevation, so temperatures at sea level are warmer than temperatures on mountaintops at the same latitude.

Solar energy input determines atmospheric circulation patterns

When a parcel of air is warmed, it expands (that is, its molecules move farther apart) and, because it is less dense than cool air,

54.1 Solar Energy Input Varies with Latitude The angle of incoming sunlight affects the amount of solar energy that reaches a given unit of Earth's surface. This view shows early summer in the Northern Hemisphere; the angle of sunlight on the hemispheres will shift as the seasons change.

54.2 Air Circulation in Earth's Atmosphere

Solar energy drives surface air patterns. Moist, warm air rises and releases moisture as precipitation. Cool, dry air descends, absorbing moisture from the atmosphere and surface.

the warm air rises. As it rises, however, it cools because there are fewer molecules to retain heat. Cool air cannot hold as much moisture as warm air, so the expanding cooling air releases moisture in the form of precipitation. Air in the region surrounding the equator receives the greatest input of solar energy. As this tropical air warms, it rises, cools, and releases large amounts of rainfall. And, as this warm air rises into the atmosphere, it is replaced by surface air flowing in from the north and south (**Figure 54.2**).

The air that moves from the north and south into the equatorial tropics is replaced by air from aloft that descends at latitudes of roughly 30°N and 30°S, having traveled away from the equator high in the atmosphere. This air, which cooled and lost its moisture as it rose, now descends, warms, and *takes up* moisture rather than releasing it. Earth's great deserts, such as the Sahara of Africa, the Gobi of China, and the deserts of Australia and the American southwest are located at these latitudes.

At about 60° latitude, air rises again and moves either toward or away from the Equator. At the poles, where there is little solar energy input, air descends again. These cyclic movements of air masses are largely responsible for the prevailing wind patterns at Earth's surface.

Global oceanic circulation is driven by wind patterns

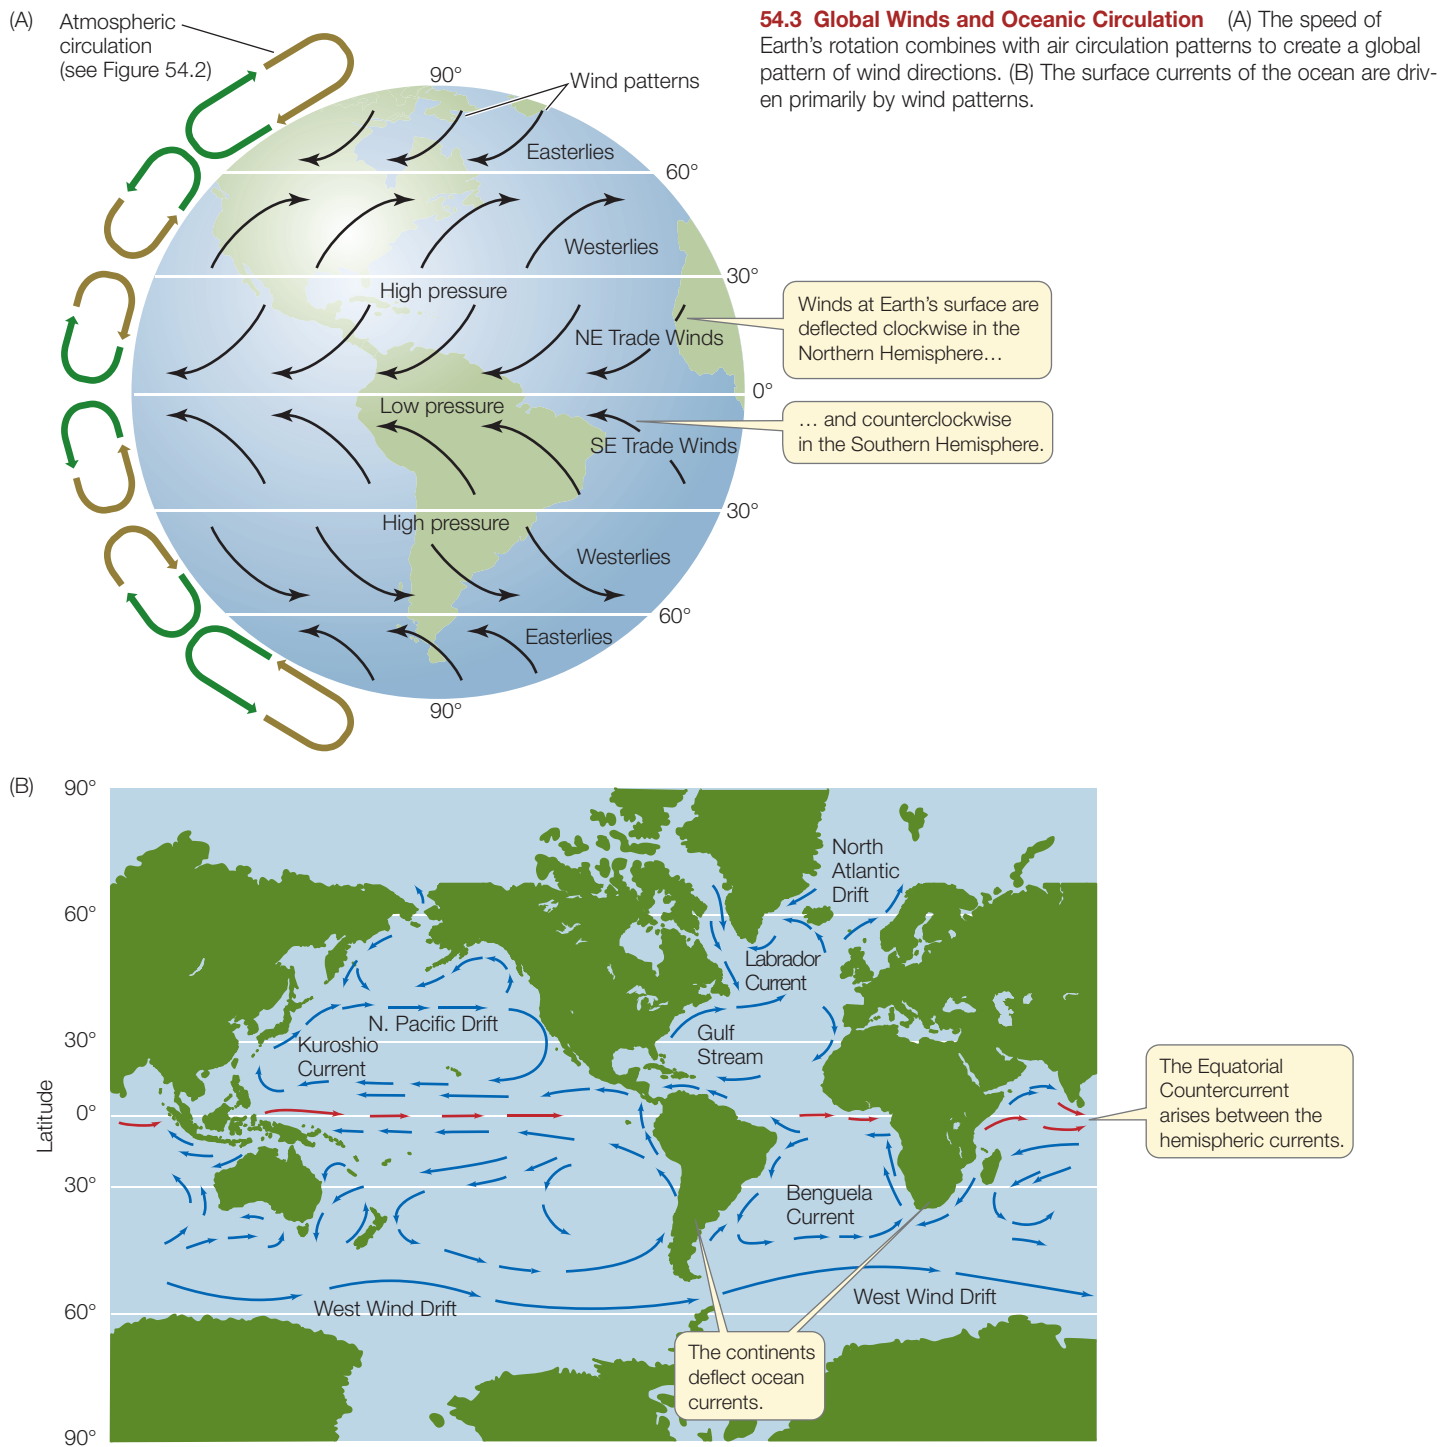

The rotation of Earth on its axis also influences prevailing winds. The velocity of rotation is fastest at the equator, where Earth's diameter is greatest, and slowest close to the poles. A stationary air mass has the same rotational velocity as does the Earth at the same latitude. As an air mass moves toward the equator, however, its rotational movement becomes slower than that of Earth beneath it. Conversely, the rotational movement of an air mass moving poleward is faster than that of the surface beneath it. Therefore, moving air masses are deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. Air masses moving toward the equator from the north and south veer to become the northeast and

southeast *trade winds*, respectively. Air masses moving away from the equator also veer, becoming the *westerly* winds that prevail at mid-latitudes (**Figure 54.3A**).

Incoming solar radiation also affects patterns of water movement in Earth's oceans. Solar energy heats the atmosphere and powers the wind, which in turn, through frictional drag, moves the water it blows over (**Figure 54.3B**). Thus global air circulation patterns drive the circulation patterns of surface ocean waters, known as *currents*. The trade winds, for example, cause currents to converge at the equator and move westward until they encounter a continental land mass. At that point, the currents divide, with some water moving north and some moving south along continental shores. As these currents move toward the poles, the water veers right in the Northern Hemisphere and left in the Southern Hemisphere, just as the winds do.

Ocean currents transport heat, and thus have a large effect on Earth's climates. The poleward movement of water that has warmed while in the tropics transfers large amounts of heat to high latitudes. The Gulf Stream, for example, brings warm water from the tropical Atlantic Ocean (including the Gulf of Mexico) north across the Atlantic to northern Europe, making the climate there considerably milder than that of corresponding latitudes in North America.

In addition to moving water laterally, the trade winds can also cause water to move vertically to influence climate. As trade winds pull surface water away from an area, deeper colder water can rise to replace it. An *upwelling* is an area where water from depths below 50 meters rises to mix with and replace warmer surface waters. The trade winds drive upwellings at the equator; other wind-driven currents create upwellings along coastlines.

Organisms adapt to climatic challenges

The climatic conditions in a region—especially temperature and water availability—act as selective agents on the organisms that live there. As a consequence, many organisms display adaptations to climatic conditions that can involve physiological, morphological, and/or behavioral specializations.

Metabolic specializations help many organisms cope with an environment that periodically becomes too hot, too cold, too dry, or short of food. These specializations are manifested in

various forms of resting states that can become a programmed part of the organism's life cycle. *Estivation* (torpor or dormancy during summer), *hibernation* (torpor or dormancy during winter), and *diapause* (the invertebrate equivalent of hibernation) are such states, characterized by dramatically reduced metabolic activity and enhanced physiological resistance to the adverse conditions (see Section 40.4). These states persist until environmental signals indicate that conditions are again conducive to growth.

To deal with extremely low temperatures, cold-hardy organisms are capable of surviving by a variety of strategies, chief among which is producing antifreezes. Microbes, sponges, Arctic fishes, and many temperate-zone insects are among the organisms that produce antifreezes to lower the freezing point of their cell contents or body fluids. One of only two flowering plant species native to Antarctica, the freeze-tolerant hairgrass (*Deschampsia antarctica*) survives by producing proteins that inhibit the formation of damaging large ice crystals. In Alaska, the wood frog (*Rana sylvatica*), the only amphibian found north of the Arctic Circle, survives temperatures of -6°C for over a month with up to 65 percent of its body fluid frozen solid (Figure 54.4A). The frog avoids damage to its cells by allowing fluids to freeze in extracellular spaces.

Adaptation to climatic conditions is often reflected in differences in morphology. For example, some endotherms living in cold climates have proportionally rounder shapes and shorter appendages than their relatives adapted to warmer climates, which gives them a smaller surface area and allows them to conserve heat more easily (see Figure 40.14). Pigmentation can also influence rates of heat loss and gain. The larvae of some hornworm moths of the genus *Manduca* are black if they hatch at temperatures below 20°C but are green if the temperature is above that threshold. Black individuals absorb more sunlight and survive at temperatures likely to be lethal to their green conspecifics. When temperature is not an issue, the cryptic green pigmentation is favored because it provides protection from predators (Figure 54.4B).

Behavioral mechanisms for temperature regulation often complement physiological and morphological adaptations, particularly among ectotherms. Basking by lizards and evaporative cooling by honeybees are just two examples. Another important behavioral adaptation to climatic conditions is changing one's location to find a more suitable microclimate. A **microclimate** is a subset of climatic conditions in a small specific area that generally differ from those in the environment at large. For example, desert lizards maintain their body temperature by spending time in an underground burrow and moving about the surface only as dictated by environmental conditions (see

Figure 40.10). While surface temperatures may fluctuate wildly, the microclimate of the burrow is buffered against such changes.

In addition to such localized movements, long-distance movements can be key adaptations to climatic challenges. Many organisms seek new places to live when local conditions deteriorate. If repeated seasonal changes alter an environment in predictable ways, organisms may evolve life cycles that appear to anticipate those changes. *Migration*, one response to such cyclic environmental changes is discussed in Section 53.5.

Most changes in the abiotic environment, both short-term and long-term, happen independently of anything organisms do. Storms rage, the seasons come and go, and glaciers advance and retreat uninfluenced by the organisms that must deal with their effects. Other environmental changes, however, are influenced by the activities of organisms. As we will see in subsequent chapters, many significant changes in the environment to which organisms must adapt are caused by other organisms, and many characteristics of organisms have been shaped by the history of such interactions.

54.2 RECAP

Latitudinal differences in solar energy input create patterns of atmospheric circulation, and those prevailing winds drive oceanic circulation. Organisms deal with climatic challenges by means of physiological, morphological, and behavioral adaptations.

- How does latitudinal variation in solar energy input drive global air circulation patterns? See pp. 1142–1143 and Figure 54.2
- How do global air circulation patterns drive ocean currents? See p. 1143 and Figure 54.3

The tremendous variation in Earth's climates has given rise to many different assemblages of organisms. Ecologists have found it useful to classify and name environments based on their ecological similarities.

(A) *Rana sylvatica*

(B) *Manduca quinquemaculata*

54.4 Evolutionary Adaptations to Climate

(A) Wood frogs can survive frigid Alaskan winters by allowing up to 65 percent of their body fluids to freeze. (B) The larvae of some hornworm moths (genus *Manduca*) have adaptive pigmentation. The black phenotype allows the caterpillar to absorb sunlight more efficiently and survive at cooler temperatures; the cryptic green phenotype is favored if temperature is not an issue.

54.3 What Is a Biome?

A **biome** is an environment that is defined by its climatic and geographic attributes and characterized by ecologically similar organisms, particularly its dominant plants. By providing three-dimensional structure and by modifying microclimates near the ground, the dominant plants of a terrestrial environment strongly influence the lives of the other organisms living there. In contrast, aquatic environments, discussed in Section 54.5, are less dependent on plants for their structure.

The same biome may be present in several widely separated places across the globe, depending in large part on the distribution of suitable climatic conditions (**Figure 54.5**). The identities of the species in geographically separate regions may differ, but through convergent evolution in response to similar selective forces (see Section 22.1), organisms in similar biomes are likely to share many physiological, morphological, and behavioral adaptations.

The distributions of biomes are determined largely by annual patterns of temperature and rainfall. In some biomes, such

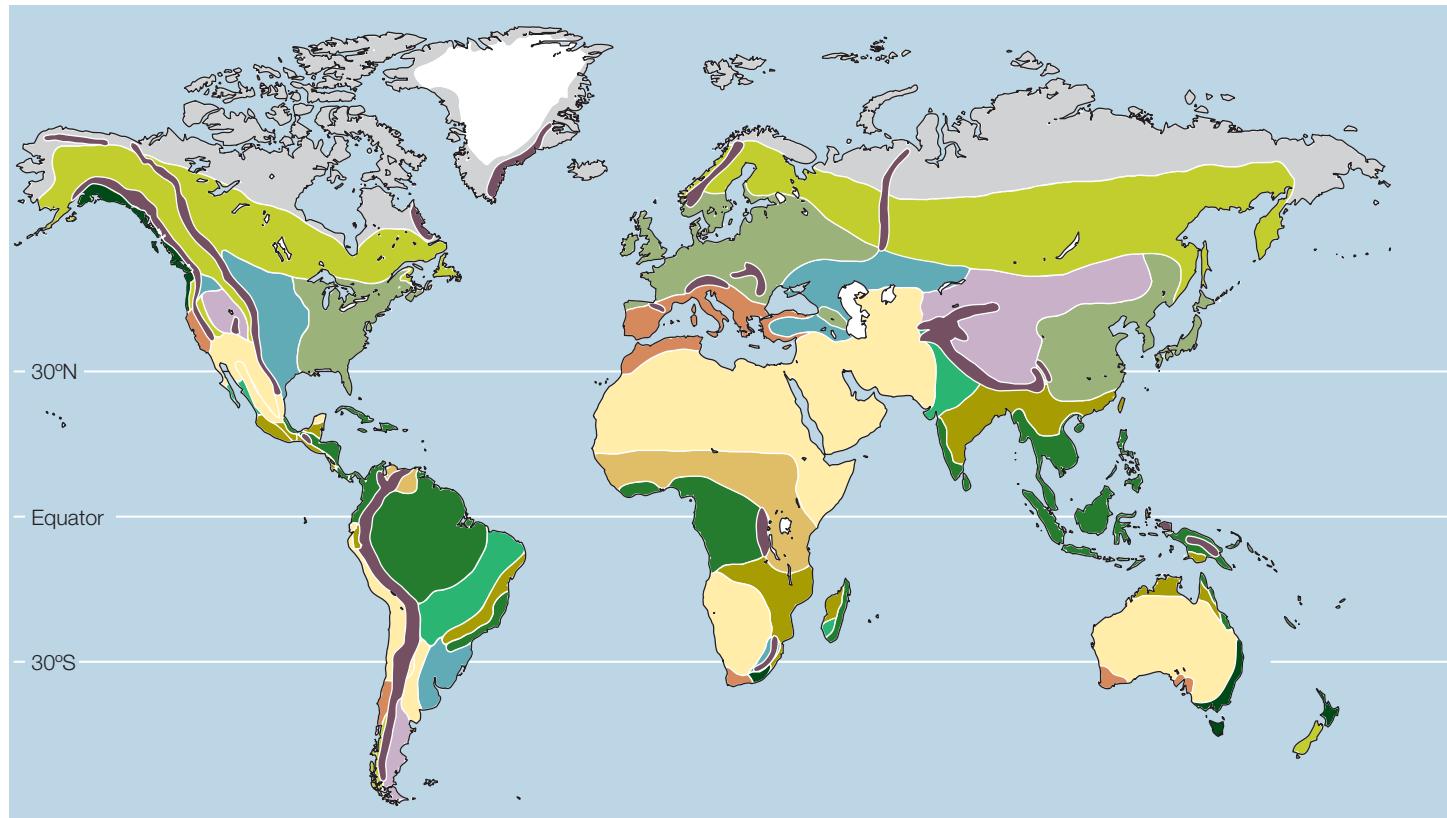

as temperate deciduous forest, precipitation is relatively constant throughout the year, but temperature varies strikingly between summer and winter. In other biomes, both temperature and precipitation change seasonally. In the tropics, seasonal temperature fluctuations are small and annual cycles are dominated by wet and dry seasons. Tropical biome types are determined primarily by the length of the dry season.

The descriptions of biomes presented here are very general and fall far short of encompassing the variation that can be found within each biome. Furthermore, the boundaries between biomes tend to be arbitrary. Although sometimes an abrupt change is apparent in a landscape, more often one biome gradually merges into another. Despite these uncertainties, recognizing the major biomes of the world is useful inasmuch as these environments share ecological attributes irrespective of their location.

54.5 The Global Distribution of Biomes The distribution of biomes is based primarily on vegetation patterns and is strongly influenced by annual patterns of temperature and precipitation.

TUNDRA

Alpine tundra: Giant groundsel (*Senecio brassica*) on the slopes of Mt. Kilimanjaro, Tanzania

Arctic tundra: Denali National Park, Alaska

Community composition

Dominant plants

Perennial herbs and small shrubs

Species richness

Plants: Low; higher in tropical alpine

Animals: Low; many birds migrate in for summer; a few species of insects abundant in summer

Soil biota

Few species

The feathery feet and white plumage of the willow ptarmigan (*Lagopus lagopus*) are adaptations to the snows of the Arctic tundra in Manitoba.

Tundra is found at high latitudes and high elevations

The **tundra** biome is found in the Arctic and at high elevations in mountains at all latitudes. In Arctic tundra, the vegetation consists of low-growing perennial plants and is underlain by *permafrost*—soil permeated with permanently frozen water. The top few centimeters of the soil thaw during the short summers, when the sun may be above the horizon 24 hours a day. Even though there is little precipitation, lowland Arctic tundra is wet because water cannot drain through the permafrost.

Alpine tundra is found at high elevations outside polar regions. *Tropical alpine tundra* is not underlain by permafrost, so

photosynthesis and most other biological activities continue (albeit slowly) throughout the year. A variety of plant growth forms are present in tropical alpine tundra, including low-growing shrubs, rosette perennials, and grasses.

Many tundra plants have hairy leaves that trap heat; the flowers of some species move over the course of the day, tracking the sun's warmth. Most animals are either summer migrants or are dormant for much of the year. Resident birds and mammals, such as the ptarmigan and Arctic fox, have thick fur or feathers that may change color from brown in summer to white in winter.

BOREAL and TEMPERATE EVERGREEN FOREST

Southern beech (*Nothofagus*) forest, Fiordland National Park, New Zealand

Bull moose (*Alces alces*) in boreal forest, Alberta, Canada

Community composition

Dominant plants

Trees, shrubs, and perennial herbs

Species richness

Plants: Low in trees, higher in understory

Animals: Low, but with summer peaks in migratory birds

Soil biota

Very rich in deep litter layer

The boreal owl (*Aegolius funereus*) feeds on insects and small birds and mammals of the coniferous evergreen forests of Europe and North America. The owl lives in the forests year-round, dispersing occasionally when food becomes extremely scarce.

Evergreen trees dominate boreal forests

The **boreal forest** biome (also known as *taiga*) occurs at latitudes below Arctic tundra and at elevations below alpine tundra on temperate-zone mountains. Winters are long and very cold; summers are short, although often relatively warm. The short summer favors trees with evergreen leaves that are ready to photosynthesize as soon as temperatures warm.

The evergreen forests of the Northern Hemisphere are dominated by coniferous gymnosperm species such as spruce and fir. The leaves of conifers are needlelike rather than flat; their reduced surface area cuts down on evaporative water loss. In

the Southern Hemisphere forests, the dominant trees are southern beeches (*Nothofagus*), some of which are evergreen.

The dominant mammals of the boreal forest, such as moose and hares, eat leaves, but the seeds in conifer cones support a variety of rodents, birds, and insects. While some small mammals hibernate in winter, voles, lemmings, and mice remain active in snow tunnels, providing food for predators such as foxes and owls.

Temperate evergreen forests grow along the coasts of continents in both hemispheres at middle to high latitudes, where winters are mild but wet and summers are cool and dry.

TEMPERATE DECIDUOUS FOREST

Fallen oak leaves on the winter forest floor, New York State

Black bears (*Ursus americanus*) are common in North American deciduous forestsMourning cloak butterflies (*Nymphalis antiopa*) overwinter as adults, settled in crevices and under tree bark in the deciduous forests of eastern North America. Their early appearance is a harbinger of spring.

Community composition

Dominant plants

Trees and shrubs

Species richness**Plants:** Many tree species in southeastern U.S. and eastern Asia, rich shrub layer**Animals:** Rich; many migrant birds, richest amphibian communities on Earth, rich summer insect fauna**Soil biota**

Rich

Temperate deciduous forests change with the seasons

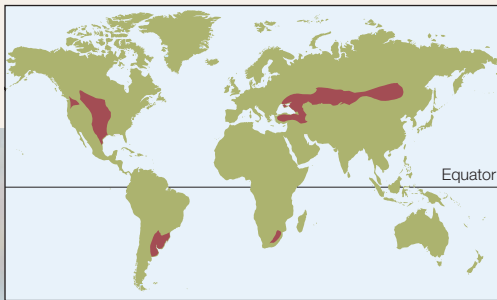

The **temperate deciduous forest** biome is found in eastern North America, eastern Asia, and Europe. Temperatures in these regions fluctuate dramatically between summer and winter, although precipitation is fairly evenly distributed throughout the year. *Deciduous* trees, which dominate these forests, lose their leaves during the cold winters and produce new leaves that photosynthesize rapidly during the warm, moist summers.

Many more tree species live here than in boreal forests. The temperate forests richest in species are those of the southern Appalachian Mountains of the United States and the ones found

in eastern China and Japan—areas that were not covered by glaciers during the Pleistocene. Many plant genera are shared among the three geographically separate regions with a deciduous forest biome.

Although many animals are permanent residents of deciduous forests, some (including many birds) migrate to escape the winter cold. Others that remain through the winter acquire massive fat stores in fall and hibernate, often in underground burrows. Many resident insects pass the winter in a state of diapause, the onset of which is triggered by a decreasing number of daylight hours, a reliable predictor of the onset of winter.

TEMPERATE GRASSLANDS

Przewalski's horse in Khustain Nuruu National Park, Mongolia

American bison herd grazing shortgrass prairie, North Dakota

Community composition

Dominant plants

Perennial grasses and forbs

Species richness

Plants: Fairly high

Animals: Relatively few birds because of simple structure; mammals fairly rich

Soil biota

Rich

The flightless Darwin's rhea (*Rhea pennata*) is adapted to grazing the grasslands of the Andean plateau (the Altiplano) of Chile and Peru. It is also found on the pampas of Argentina.

Temperate grasslands are widespread

Temperate grasslands are found in many parts of the world, all of which are relatively dry for much of the year. Most grasslands, such as the pampas of Argentina, the veldt of South Africa, and the Great Plains of North America, have hot summers and relatively cold winters. In some grasslands, most of the precipitation falls in winter (as in California grasslands); in others, the majority falls in summer (as in the Great Plains and the Russian steppe).

Grassland vegetation is structurally simple but rich in species of perennial grasses and *forbs* (herbaceous plants other than

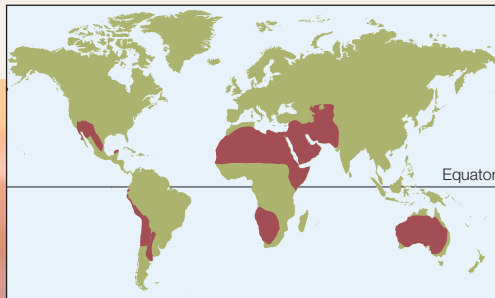

grasses). This abundance of plant biomass supports herds of large grazing mammals. Grassland plants are adapted to grazing and to fire. They store much of their energy underground and sprout quickly after being burned or grazed. There are comparatively few trees in temperate grasslands because they cannot survive the periodic fires.

The topsoil of grasslands is usually rich and deep, and thus exceptionally well suited to growing crops, particularly grains such as corn and wheat. As a consequence, most of the world's temperate grasslands have been turned over to agriculture and no longer exist in their natural state.

HOT DESERT

Gemsbok (*Oryx gazella*) on the dunes, Namib-Naukluft National Park, Namibia

Succulents such as agave, candelabra, and cardon characterize the deserts of the North American southwest

Community composition

Dominant plants

Many different growth forms

Species richness

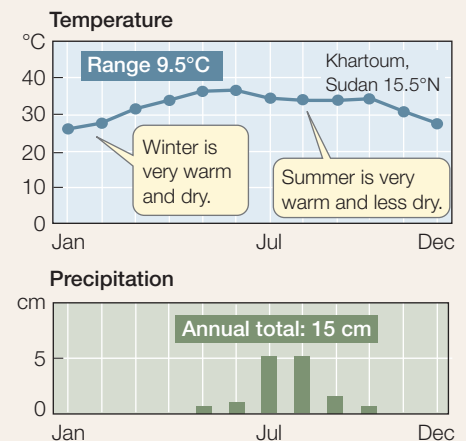

Plants: Moderately rich; many annuals
Animals: Very rich in rodents; richest bee communities on Earth; very rich in reptiles and butterflies

Soil biota

Few species

The fog-basking beetle (*Onymacris unguicularis*) retrieves the water it needs to survive from the morning fogs of Africa's Namib Desert.

Hot deserts form around 30° latitude

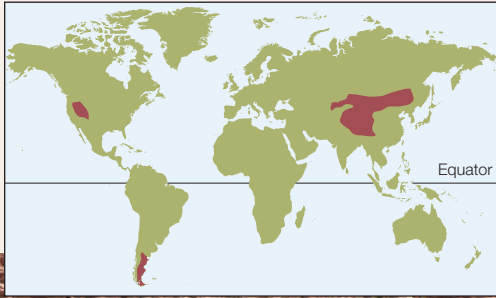

The **hot desert** biome is found in two belts, centered around latitudes 30°N and 30°S (see Figure 54.2). The driest regions, where rains rarely penetrate, are far from the oceans. Examples of this are in the center of Australia and the middle of the Sahara in Africa.

The structural features of desert plants reflect the need to conserve water. These include taproots that reach water far below the surface; a shallow but extensive root system that absorbs water quickly after rare rain events; and small, wax-covered leaves that open their stomata only at night. Most

perennials go dormant during dry seasons, growing quickly as soon as rains return. Their seeds tend to be heat- and drought-resistant and accumulate in a dormant state in the soil.

Small animals are inactive during the hottest part of the day, remaining in underground burrows. When the heat becomes extreme, many small invertebrates estivate. Desert mammals have physiological adaptations for conserving water, including reduced number of sweat glands and kidneys that produce highly concentrated urine. Many desert animals require no water beyond what they can extract from the carbohydrates in their food.

COLD DESERT

Vicuña (*Vicugna vicugna*) family herd in Andean desert, Lauca National Park, Chile

Introduced wild donkeys (*Equus africanus asinus*) thrive in the high deserts of Utah

Community composition

Dominant plants

Low-growing shrubs and herbaceous plants

Species richness

Plants: Few species

Animals: Rich in seed-eating birds, ants, and rodents; low in all other taxa

Soil biota

Poor in species

Living in a cold desert presents special challenges to a poikilotherm. This collared lizard (*Crotaphytus* sp.) in Bluff, Utah, is warming itself by basking on a rock.

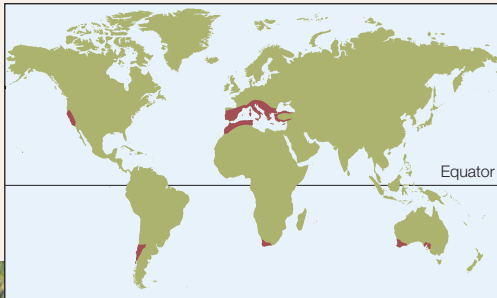

Cold deserts are high and dry

The **cold desert** biome is found in dry regions at mid- to high latitudes, especially in the interiors of continents in the rain shadows of mountain ranges. Seasonal changes in temperature are great.

Cold deserts are dominated by a few species of low-growing shrubs. The surface layers of the soil are recharged with

moisture in winter, and plant growth is concentrated in spring. Cold deserts are relatively poor in species diversity, but the plants that do grow there tend to produce large numbers of seeds, supporting many species of seed-eating birds, ants, and rodents. Burrowing behavior is widespread among cold desert dwellers, but, in contrast with hot desert animals, they burrow to escape cold temperatures, not excessive heat.

CHAPARRAL

Fynbos in the spring, a unique chaparral vegetation of South Africa's Cape Peninsula

A coyote (*Canis latrans*) in the chaparral of California's Santa Cruz Mountains

Community composition

Dominant plants

Low-growing shrubs and herbaceous plants

Species richness

Plants: Extremely high in South Africa and Australia

Animals: Rich in rodents and reptiles; very rich in insects, especially bees

Soil biota

Moderately rich

Two fynbos species, the Cape sugarbird (*Promerops caffer*) and its nectar source, the pincushion protea (*Leucospermum cordifolium*) in the Helderberg Nature Reserve, South Africa

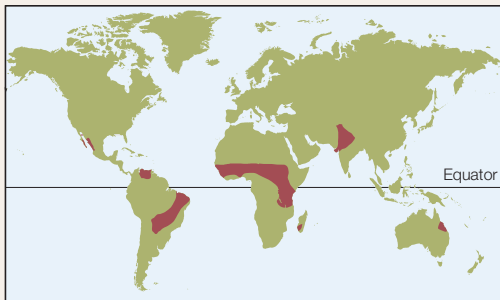

Chaparral has hot, dry summers and wet, cool winters

The **chaparral** biome is found on the western sides of continents at mid-latitudes (around 40°) where cool ocean currents flow offshore. Winters in this biome are cool and wet; summers are warm and dry. Such climates are found in the Mediterranean region of Europe, coastal California, central Chile, extreme southern Africa, and southwestern Australia.

The dominant plants of chaparral vegetation are low-growing shrubs and trees with tough evergreen leaves that conserve water. The shrubs carry out most of their growth and photosynthesis in early spring, when insects are active and birds breed. Many

chaparral species produce strong-smelling defensive chemicals to reduce losses of hard-to-replace foliage to herbivores. Annual plants are abundant and produce large quantities of seeds that fall onto the soil, supporting many small rodents, most of which store seeds in underground burrows. Burrowing to avoid mid-day heat and nocturnal foraging are strategies used by many chaparral animals. Chaparral vegetation is adapted to periodic fires; the seeds of some species do not germinate until after they have survived a fire. Many shrubs of Northern Hemisphere chaparral produce bird-dispersed fruits that ripen in late fall, when large numbers of migrant birds arrive from the north.

THORN FOREST and TROPICAL SAVANNA

Plains zebra (*Equus quagga*) in large herd of blue wildebeest (*Connochaetes taurinus*) on the Tanzania savanna, Africa

Ocotillo species native to Madagascar dominate this thorn forest

Community composition

Dominant plants

Shrubs and small trees; grasses

Species richness

Plants: Moderate in thorn forest; low in savanna

Animals: Rich mammal faunas; moderately rich in birds, reptiles, and insects

Soil biota

Rich

Termite colonies build huge mounds on the African savanna, providing a food source for mammals such as this baboon (*Papio* sp.).

Thorn forests and tropical savannas have similar climates

The **thorn forest** and **tropical savanna** biomes are found at latitudes below the hot deserts of Africa, South America, and Australia. Little or no rain falls in winter, but rainfall may be heavy during summer. Thorn forests contain many plants similar to those found in hot deserts. The dominant plants are spiny shrubs and small trees, many of which drop their leaves during the long, dry winter. Trees of the genus *Acacia* are common in thorn forests and savannas worldwide. In Africa, *Andansonia* (baobab) trees are also a hallmark of this biome.

Savanna is characterized by expanses of grasses and grasslike plants with scattered individual trees. The largest tropical savannas are found in central and eastern Africa, where they are populated by herds of grazing and browsing mammals and the large carnivores that prey on them. Grazers and browsers maintain the savannas. If savanna vegetation is not grazed, browsed, or burned, it typically reverts to dense thorn forest. The migration of vast herds of African herbivores in search of “greener pastures” during the dry season is another characteristic of this impressive region.

TROPICAL DECIDUOUS FOREST

A forest canopy of pijo trees (*Cavanillesia platanifolia*) during the dry season in Cerro Blanco on the Ecuadoran coast

Bengal tiger (*Panthera tigris tigris*) in the forests of Bandhavgarh, India.

Community composition

Dominant plants

Deciduous trees

Species richness

Plants: Moderately rich in tree species

Animals: Rich mammal, bird, reptile, and amphibian communities; rich in insects

Soil biota

Rich, but poorly known

The rufous hummingbird (*Selasphorus rufus*) is a seasonal migrant that spends winters in the tropical deciduous forests of Guerrero, Mexico.

Tropical deciduous forests occur in hot lowlands

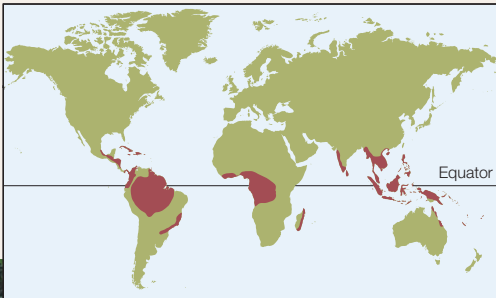

As the length of the rainy season increases toward the Equator, the **tropical deciduous forest** biome replaces thorn forest. Tropical deciduous forests have taller trees and fewer succulent plants than thorn forests, and they support a much greater number of plant and animal species. Most of the trees, except for those growing along rivers, lose their leaves during the long, hot dry season. Activity picks up in the rainy season; many plants flower while they are still leafless.

Most plant species in this biome are pollinated by animals. In the Sierra Madre Occidental, a mountain range in the extreme

southwestern United States extending into western Mexico, tropical deciduous forests are part of a “nectar corridor”: a series of patches of flowering plants that provide refueling stops for long-distance migrants traveling north from overwintering sites to breeding sites in the Rocky Mountains. Among the migratory pollinators that fly this corridor are lesser long-nosed bats, white-winged doves, and rufous hummingbirds.

The soils of this biome are among the best in the tropics for agriculture because they contain more nutrients than the soils of wetter areas. As a result, most tropical deciduous forests worldwide have been cleared for agriculture and grazing.

TROPICAL EVERGREEN FOREST

The canopy of an Ecuadoran tropical forest, seen from above

Plants: Extremely high**Animals:** Extremely high in mammals, birds, amphibians, and arthropods

Soil biota

Very rich but poorly known

The three-toed sloth (*Bradypus variegatus*) is almost totally arboreal, spending its life in the rainforest canopies of Central and South America.

Tropical evergreen forests are rich in species

The **tropical evergreen forest** biome (commonly called the rainforest) is found in Equatorial regions where total rainfall exceeds 250 centimeters annually and the dry season lasts no longer than 2 or 3 months. With no seasons unsuitable for growth, it is the most species-rich of all biomes, with up to 500 species of trees per km². Although these forests cover less than 2 percent of Earth's surface, they are home to over half of all known species.

Along with the immense number of species they support, tropical evergreen forests have the highest overall productivity of all ecological communities. However, most mineral nutrients are tied

up in the vegetation. The soils usually cannot support agriculture without massive applications of fertilizers. These forests are home to many *epiphytes*, plants that grow on other plants, deriving their nutrients and moisture from air and water rather than soil.

Tropical evergreen forests provide humans with a dazzling range of products, including fruits, nuts, medicines, fuel, pulp, and furniture wood. Many more useful species undoubtedly await discovery, as only a small proportion of this biome's species have been inventoried. The rainforests, however, are currently being deforested or converted to agriculture at a rate of almost 20 million hectares per year.

Major topographic features, such as mountains or large lakes, may have regional effects on temperature and precipitation. When prevailing winds bring air masses into contact with a mountain range, for example, the air rises to pass over the mountains, expanding and cooling as it does so. Thus clouds frequently form on the windward side of mountains (the side facing into the winds) and release moisture as rain or snow. On the leeward side (opposite from the direction of the winds), the now-dry air descends, warms, and once again picks up moisture. This pattern often results in a dry area called a **rain shadow** on the leeward side of a mountain range (**Figure 54.6**).

Biome distribution is not determined solely by temperature

Although warm temperatures and high precipitation support greater numbers of species than do colder, drier conditions, other climatic factors—particularly soil characteristics and the occurrence of wildfires—also influence the structure and life cycles of the dominant vegetation in an area and, consequently, the ecological attributes of the other organisms living there. For example, the plants of Australian deserts grow on extremely nutrient-poor soils and thus have difficulty growing new foliage. Such plants often protect their leaves against consumers by producing large quantities of digestibility-reducing chemicals. Such leaves are generally left uneaten, and when they senesce they drop to the ground, providing an abundance of highly flammable litter to feed the intense fires that periodically sweep across the landscape. As a result, succulent plants, which are easily killed by fires, are not found in Australia, although they are common in deserts on other continents (see p. 1151).

54.6 A Rain Shadow Mean annual precipitation tends to be lower on the leeward side of a mountain range than on the windward side.

54.3 RECAP

Ecologists recognize a number of terrestrial environment types called biomes. The geographic distribution of biomes is determined primarily by temperature and precipitation, but is also influenced by soil characteristics and fire.

- How do temperate grasslands differ from tropical savannas? **See pp. 1150 and 1154**
- What primary factor distinguishes a tropical biome? **See pp. 1154–1156**

Climatic conditions explain why chaparral vegetation is confined to the western coasts of continents at mid-latitudes, but it cannot explain why the chaparral in California and the chaparral in South Africa have no species in common. To explain the distribution of species on Earth, another aspect of the abiotic environment—geological history—must be taken into account.

54.4 What Is a Biogeographic Region?

Climate interacts with local abiotic features to influence where and how organisms live, but these are not the only factors that determine where organisms can be found. Evolutionary history—where and when groups of organisms originated and diverged—is key to determining the distributions of organisms, which in turn is profoundly influenced by geological history.

Geological history influenced the distribution of organisms

Until European naturalists traveled the globe, they had no way of knowing how organisms were distributed elsewhere. Alfred Russel Wallace, who along with Charles Darwin advanced the idea that natural selection could account for the evolution of life on Earth (see Section 21.1), was one of those global travelers. Wallace returned to England in 1862 after seven years in the Malay Archipelago, where he noticed some remarkable patterns in the distributions of organisms. For example, he described the dramatically different birds that inhabited the adjacent islands Bali and Lombok:

In Bali we have barbets, fruit-thrushes and woodpeckers; on passing over to Lombok these are seen no more, but we have an abundance of cockatoos, honeysuckers, and brush-turkeys, which are equally unknown in Bali, or any island further west. The strait here is fifteen miles wide, so that we may pass in two hours from one great division of the earth to another, differing as essentially in their animal life as Europe does from America.

Wallace pointed out that these differences could not be explained by climate or by soil characteristics, because in those respects Bali and Lombok are essentially identical.

Wallace saw that, based on the distributions of plant and animal species, he could draw a line that divided the Malay Archipelago into two distinct halves (**Figure 54.7**). He correctly de-

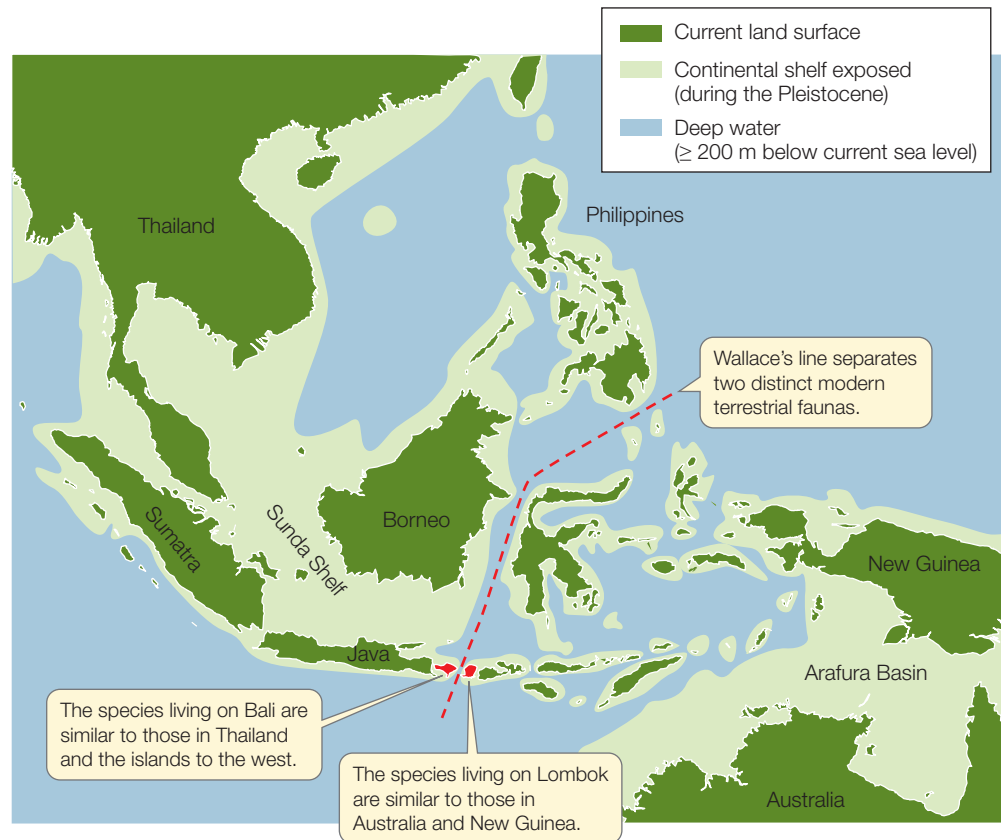

54.7 Wallace's Line Wallace's line corresponds to a deep-water channel between the islands of Bali and Lombok. This channel would have blocked the movement of terrestrial organisms even during the Pleistocene glaciations, when sea level was 100 meters lower than it is today.

duced that the dramatic differences in flora and fauna were related to the depth of the channel separating Bali and Lombok. This channel is so deep that it would have remained full of water, and thus would have been a barrier to the movement of terrestrial animals, even during the glaciations of the Pleistocene era, when sea level dropped more than 100 m and Bali and the islands to the west were connected to the Asian mainland.

With these insights, Wallace established the conceptual foundations of **biogeography**, the scientific study of the patterns of distribution of populations, species, and ecological communities across Earth. In *The Geographical Distribution of Animals*, published in 1876, he detailed the factors known at the time that influence the distributions of animals, including past glaciation, land bridges, deep ocean channels, and mountain ranges. He earned some measure of scientific immortality in that the Malay discontinuity that first piqued his curiosity is known to this day as “Wallace’s line.”

The biotas of different parts of the world differ enough to allow us to divide Earth into several continental-scale areas, called **biogeographic regions** (Figure 54.8), each containing characteristic assemblages of species occupying many different biomes. The boundaries of these biogeographic regions are drawn where assemblages of species change dramatically over short distances. Wallace’s line, for example, separates the Oriental biogeographic region from the Australasian biogeographic region. The biotas of biogeographic regions differ because oceans, mountains, deserts, and other barriers restrict the dispersal of organisms from one region to another. Although organisms do disperse between adjacent bio-

54.8 Earth's Biogeographic Regions The major biogeographic regions are separated by climatic, topographic, and/or aquatic barriers to dispersal that cause their biotas to differ strikingly from one another.

geographic regions, such interchanges have not been frequent or massive enough to eliminate the striking differences between them.

GO TO Web Activity 54.1 • Major Biogeographic Regions

Most species are confined to a single biogeographic region. A species found only within a certain region is said to be **endemic** to that region. Remote islands typically have distinctive endemic biotas because water barriers limit opportunities for

54.9 Madagascar's Endemic Species The majority of the vascular plant and vertebrate species found on the island of Madagascar are found nowhere else on Earth. Unique reptile and insect species also abound there.

Adansonia grandidieri (giant baobab tree)

climbing *Alluaudia procera* (Madagascar ocotillo)

Chamaeleo parsonii
(chameleon)

Trachelophorus giraffa (giraffe-necked weevil)

most species to colonize them. For example, nearly all the species of vascular plants and vertebrates on Madagascar, a large island 400 km off the eastern coast of Africa, are endemic to that island (**Figure 54.9**). Regions like Madagascar that are home to large numbers of endemics are classified as “biodiversity hotspots” (see Section 59.4).

Two scientific advances changed the field of biogeography

For many decades after observing that the biotas of the major biogeographic regions are strikingly different, biogeographers speculated about the causes of these differences but the field remained primarily descriptive. It was not until the second half of the twentieth century that two scientific advances transformed biogeography into a dynamic, multidisciplinary field:

the acceptance of the theory of continental drift, and the development of phylogenetic taxonomy.

CONTINENTAL DRIFT Prior to the mid-nineteenth century, most people believed that Earth was young and had changed little over time. No one at that time imagined that organisms—much less the continents themselves—had moved. But that continents can and do move was confirmed when geological evidence of continental drift was eventually discovered (see Section 25.2).

During the Triassic period, the supercontinent Pangaea broke into two great land masses, Laurasia and Gondwana (see Figure 25.12), which subsequently separated into the continents we know today. Those groups of organisms that are represented on two or more continents are believed to be ancient groups whose ancestors were distributed widely over these great landmasses before they broke apart. After the breakup, however, their de-

(A)

54.10 *Nothofagus* Has a Gondwanan Distribution The modern range of southern beeches is best explained by their origin in Gondwana during the Cretaceous. Continental drift resulted in the distribution of *Nothofagus* in South America, New Zealand, and the islands of the South Pacific.

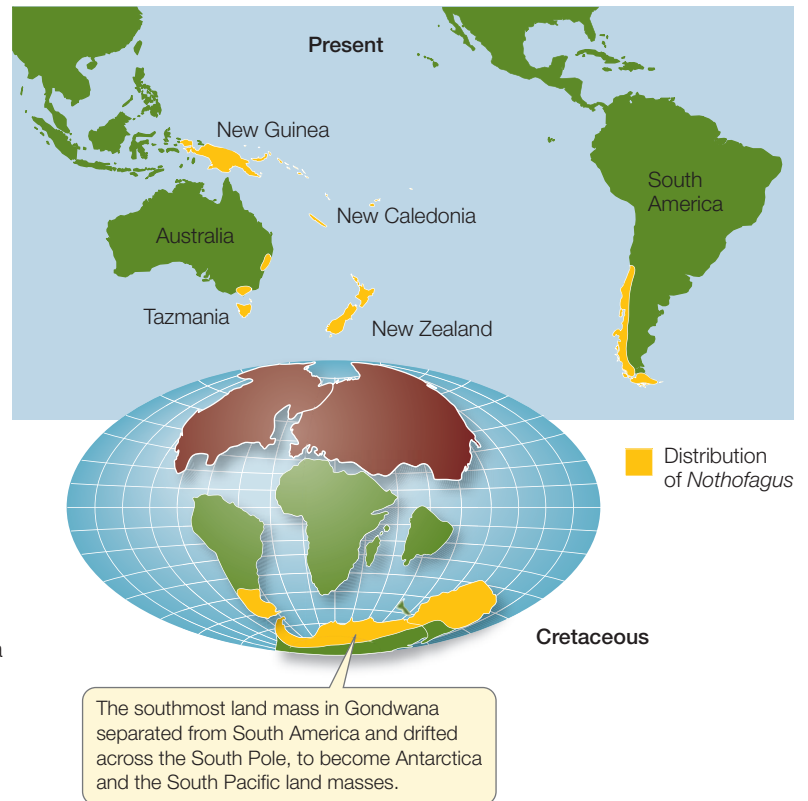

scendants evolved independently, so groups that did not originate until after that time have more discrete distributions. Thus continental drift is at least partly responsible for the existence of the seven regions shown in Figure 54.8.

Continental drift also explains certain biogeographic distributions that would otherwise be difficult to understand. For example, the southern beeches—trees of the genus *Nothofagus*—are found in both the Neotropical and the Australasian biogeographic regions. Their distribution suggests that the genus originated in Gondwana during the Cretaceous period and was geographically separated by the breakup of that land mass (Figure 54.10).

What evidence do we have that *Nothofagus* did not simply leapfrog from one biogeographic region to another? Fossilized *Nothofagus* pollen from 55–34 million years ago has been found in Australia, New Zealand, western Antarctica, and South America, suggesting that *Nothofagus* was once continuously distributed across a single land mass. Moreover, the modern distribution of aphid genera that feed exclusively on *Nothofagus* parallels the distribution of the trees. There are no air or water currents between Chile and New Zealand that would be likely to disperse insects, indicating that the aphids arose at a time when their host plants grew on a common land mass.

PHYLOGENETIC TAXONOMY As we saw in Chapter 22, taxonomists have developed powerful methods of reconstructing the phylogenetic relationships among organisms. Biogeographers have adapted these methods to help them answer biogeographic questions. Biogeographers can transform phylogenetic trees into **area phylogenies** by replacing the names of the taxa on a tree with the names of the places where those taxa now live or once lived.

(B)

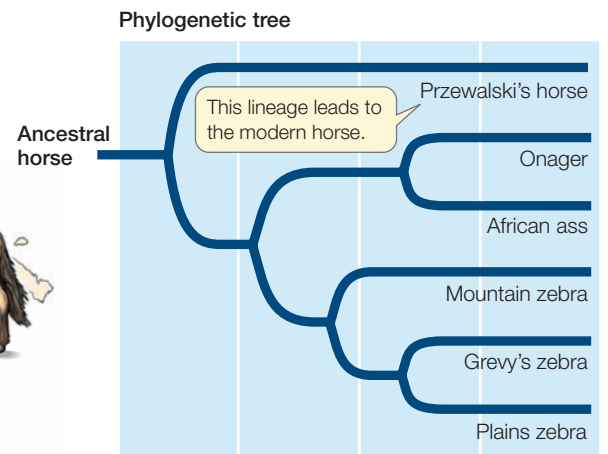

Suppose, for example, we wonder why zebras, which are members of the horse family (Equidae), live in Africa when the fossil record indicates that the Equidae evolved in North America. An area phylogeny of living species suggests that the ancestors of today's horses dispersed from North America to Asia, and then from Asia to Africa, and that the subsequent speciation of zebras took place entirely in Africa (Figure 54.11).

Biotic interchange follows fusion of land masses

Geological events not only separate land masses, but may also bring them together. When formerly separated land masses fuse, as may happen through sea level changes or continental drift, species from two different biotas may disperse into a region they had not previously inhabited. This phenomenon is called **biotic interchange**.

A great biotic interchange of mammals occurred when the Central American land bridge formed about 4 million years ago, connecting North and South America for the first time in about 65 million years. While the two continents were separated, their mammalian faunas had diverged greatly. Many of these divergent species dispersed across the newly established land bridge. Only a few South American species—the porcupine, nine-banded armadillo, and Virginia opossum—became established north of the tropical forests of Mexico. However, many North American mammals—rabbits, mice, foxes, bears, raccoons, weasels, cats, tapirs, peccaries, camels, and deer—successfully colonized South America (Figure 54.12).

54.11 Taxonomic Phylogeny to Area Phylogeny The conversion of a phylogenetic tree to an area phylogeny helps biogeographers explain how the current distribution of a taxon came about.

Vicariant events influence distribution patterns

The appearance of a physical barrier to dispersal that splits the range of a species is called a **vicariant event**. A vicariant event divides the species into two or more discontinuous populations, even though no individuals have dispersed to new areas. If, however, members of a species cross an existing barrier and establish a new population, the discontinuous range of the species is considered to be the result of dispersal.

Given that these two major processes—vicariance and dispersal—both influence distribution patterns, how can biogeographers determine the role of each process when reconstructing the evolutionary history of a particular distribution? By

54.12 Results of a Biotic Interchange (A) The nine-banded armadillo is among only a handful of mammalian species that colonized North America from South America when the Central American land bridge formed. (B) Some species that exist today only in South America are descended from ancestors that dispersed across the land bridge from North America, including the Chacoan peccary and the guanaco (a member of the camel family).

(A) *Dasypus novemcinctus*

(B) *Catagonus wagneri*

Lama guanicoe

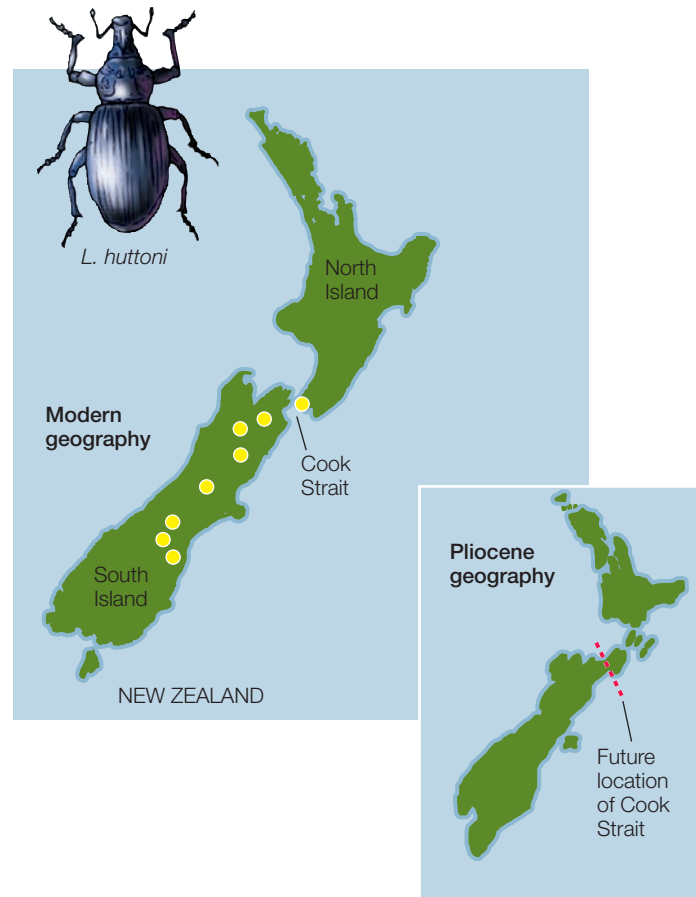

studying area phylogenies, a biogeographer may discover evidence suggesting that the distribution of an ancestral species was influenced by a vicariant event, such as continental drift or a change in sea level (see Figure 23.3). If that inference is correct, it is reasonable to assume that ancestral species in other lineages have been affected by the same event and that similar distribution patterns should therefore be seen in other taxonomic groups. Differences in distribution patterns among taxonomic groups may indicate that they responded differently to the same vicariant events, that they diverged at different times, or that they had very different dispersal histories. By analyzing such similarities and differences, biogeographers seek to discover the relative roles of vicariant events and dispersal in determining today's distribution patterns.

The parsimony principle, used to great effect in the reconstruction of phylogenies (see Section 22.2), can also be helpful in biogeographic studies. For example, the New Zealand flightless weevil *Lyperobius huttoni* is found in the mountains of South Island and on sea cliffs at the extreme southwestern corner of North Island (Figure 54.13). At first glance, its distribution might suggest that, even though this weevil cannot fly, some individuals in the distant past managed to cross Cook Strait, the 25-km body of water that separates the two islands. However, more than 60 other animal and plant species, including other flightless insects, are found on both sides of Cook Strait. Irrespective of their ability to fly, wade, or swim, it is unlikely that all 60 of these species made the same ocean crossing independently at different times over the course of their evolutionary history. In fact, geological evidence indicates that the present-day southwestern tip of North Island was once united with South Island. Thus a single vicariant event—the separation of the northern tip of South Island from the remainder of the island by the newly formed Cook Strait—could have produced the distribution pattern shared by all 60 species today.

While the concept of vicariance is easily applied in cases attributable to continental drift (due to the ease with which continental movements can be correlated with biological patterns), vicariance patterns on a smaller scale are difficult to identify unequivocally because the underlying geologic events, such as mountain uplift or glacial ice sheet movement, may have been less dramatic than continental movements. In other cases, the vicariance approach is conceptually inappropriate simply because no separation of continuous populations ever took place. There are, for example, more than 135 species of long-horned beetles endemic to the Hawaiian Islands. The islands have never been attached to any continent (they arose by volcanism from the deep ocean floor), so this distribution must have been the result of long-distance dispersal. The beetles, which are most closely related to a genus found in North and Central America, probably colonized the islands and subsequently speciated as a consequence of specializing on different host plants on different islands (see Chapter 23). Founder events must have been infrequent, because the beetles are short-lived and vulnerable to desiccation.

In fact, the present distributions of some mammalian groups provide little hint of their evolutionary origins. Canids (members of the dog family), for example, originated in North Amer-

54.13 A Vicariant Distribution Explained Yellow circles indicate the current distribution of the flightless weevil *Lyperobius huttoni*. A comparison of New Zealand's present-day geography with its geography in the Pliocene, when the southern part of today's North Island was part of South Island, suggests that a vicariant event—a physical split separating populations—explains this distribution.

ica but experienced greater evolutionary success after moving into South America; today, only four canid genera are found in North America, but there are six in South America—more than on any other continent.

Humans exert a powerful influence on biogeographic patterns

One more force capable of generating unusual distribution patterns is human activity. Of the insects found both in Europe and in North America, it has been estimated that over half have been transported between the continents by humans. Some species introductions, such as those of dung beetles to Australia, have been deliberate. That introduction turned out to be beneficial, but many others have not. Species that have been introduced to new regions inadvertently include disease vectors (such as the mosquito that transmits yellow fever), household pests (including at least four cockroach species), and crop pests that can result in economic disaster. The effects of such introductions by humans is an important topic and will be discussed at length in Chapter 59.

54.4 RECAP

Biogeographers divide Earth into seven regions, each containing unique assemblages of species. Vicariant events may generate distribution patterns by splitting the ranges of species; distribution patterns may also change when species disperse across barriers.

- What determines the boundaries of Earth's major biogeographic regions? How are these boundaries different from those of the biomes described in Section 54.3? **See p. 1146, p. 1158, and Figures 54.5 and 54.8**
- Explain how the concepts of continental drift and phylogenetic taxonomy transformed the field of biogeography. **See pp. 1159–1160**
- How do vicariance and dispersal interact to generate major biogeographic patterns? **See pp. 1161–1162**

As described in Chapter 25, life originated in the oceans. Today the three-quarters of the planet's surface that is covered with water sustains abundant life as well.

54.5 How Is Life Distributed in Aquatic Environments?

Most of Earth's aquatic environments are oceans. However, the small percentage of the watery world that consists of freshwater lakes and streams also hosts a significant proportion of Earth's aquatic organisms.

The oceans can be divided into several life zones

Earth's oceans form one large, interconnected water mass, interrupted in places by continents. Even organisms with limited swim-

ming abilities can travel long distances simply by floating with the great currents depicted in Figure 54.3. Even though the oceans have no physical barriers to dispersal, however, most marine organisms have restricted ranges. Water temperature, salinity, and food supply all vary spatially. Changes in water temperature, for example, can be barriers to dispersal because many marine organisms function well in only a narrow range of temperatures.

The striking physical and biological discontinuities within the oceans divide them into several distinct "life zones." These zones are identified principally by their distance from the surface, because depth determines how much light is available to sustain the photosynthetic organisms that make chemical energy available to consumer organisms. In both marine and freshwater environments, the depth of water reached by enough sunlight to support photosynthesis is called the **photic zone** (Figure 54.14). Approximately 90 percent of all aquatic life is found in the photic zone.

The **coastal zone**, extending from the shoreline to the edge of the continental shelf, is characterized by relatively shallow, well-oxygenated water and relatively stable temperatures and salinities. These conditions support high densities of phytoplankton, which in turn support some of the world's most important fisheries. Structure in coastal-zone communities can be provided by a variety of organisms. In warmer coastal waters, corals generate complex reef structures that support ecosystems rivaling the rainforest in diversity, and "forests" of the multicellular algal species (seaweeds and giant kelps) form along many coasts.

Near the shoreline, the area of the coastal zone that is affected by wave action is called the **littoral zone**. The principal autotrophs in this zone—sea grasses and algae—support a diversity of invertebrates as well as small fishes. The portion of the coastal zone lying between high- and low-tide levels is the **intertidal**, where tidal movements create highly variable conditions of temperature and salinity. Intertidal organisms, including clams, mussels, copepods, and burrowing worms, are alternately exposed to air or submerged on a regular basis.

Throughout most of the oceans, the dominant autotrophs are phytoplankton (photosynthetic floating protists; see Chapter 27). In the open ocean, referred to as the **pelagic zone**, the principal consumers of phytoplankton are zooplankton—mainly small crustaceans and larval stages of marine animals—which

54.14 Oceanic Life Zones The ocean's life zones are in large part determined by sunlight penetration. More than 90 percent of ocean-dwelling species live in the sunlit photic zone, which comprises less than 2 percent of the open water.

in turn support many larger free-swimming vertebrate and invertebrate species.

The ocean bottom is referred to as the **benthic zone**. Many benthic organisms are adapted to life on the seafloor substrate. They include sessile animals such as sponges, bryozoans, ribbon worms, and brachiopods (see Chapters 31 and 32), as well as motile bottom feeders such as crabs and sea slugs (see Figure 32.15C).

Where water is too deep for light to penetrate, little photosynthesis can take place, and both plant and animal diversity are low. Depths reached by less than 1 percent of incoming sunlight constitute the **aphotic zone** (including the **abyssal plain** of the deep ocean floor). Many of the organisms inhabiting these regions subsist on decaying organic matter that sinks down from the photic zone. Some produce their own light by way of bioluminescent organs (see Figure 33.13D). Even deep-ocean trenches and rift valleys support ecosystems, often sustained by chemosynthetic microbes that can metabolize the nutrients in seawater without the aid of sunlight (see Section 26.2).

Freshwater environments may be rich in species

In contrast to the vast oceans, the world's freshwater environments cover less than 3 percent of Earth's surface. However, they are home to about 10 percent of all aquatic species. Freshwater environments may be found in running water (streams and rivers) or in standing water (lakes and ponds). Like the oceans, bodies of standing water can be divided into zones based on depth and light penetration, with a littoral zone close to shore characterized by warm temperatures and high species diversity, a pelagic zone with its upper layers teeming with phytoplankton, and deeper waters below, where little light penetrates and oxygen levels are low, characterized by low diversity.

Discontinuities in the ranges of aquatic organisms are seen because most animals that live in the oceans cannot survive in fresh water, and vice versa. For example, most groups of freshwater fishes cannot tolerate salt water, so they are restricted to a single continent. They can disperse only within the connected rivers and lakes of a drainage basin or in brackish coastal waters.

Estuaries have characteristics of both freshwater and marine environments

Estuaries are bodies of water that form where rivers meet the ocean, in which salt water mixes with fresh water. Having char-

acteristics of both freshwater and marine systems, estuaries are home to many unique species, and they play an important role for other species as a conduit between marine and freshwater environments. Some salmon species that hatch in rivers, for example, spend many months in estuaries adjusting to higher salinities before swimming out to sea to grow into adults. Diversity within estuaries tends to be very high. Estuarine environments have long been an important source of human resources, not the least of which is their role in purifying groundwater. In many places around the world, however, overfishing and pollution threaten estuarine viability.

54.5 RECAP

Despite being connected, the oceans are divided into distinct regions that generate striking physical and biological discontinuities. Oceanic life zones are determined by distance from the surface, which influences how much light is available to sustain photosynthesis. Fresh waters, comprising river basins and thousands of relatively isolated lakes, are also divided into life zones according to the depth and light penetration. Estuaries are bodies of water where salt water mixes with fresh water and support many unique species.

- How does light penetration affect diversity in different life zones of the oceans? **See p. 1163 and Figure 54.14**
- How do estuaries link freshwater and marine systems, and why are these ecosystems so important? **See p. 1164**

The physical environment exerts a tremendous influence on the distribution of organisms on Earth, but to understand how and where life flourishes on Earth, it is also important to understand the influence of organisms on one another. In Chapter 55 we will consider the dynamics of populations. Chapters 56 and 57 describe how populations interact and form ecological communities. The final two chapters in the book describe global ecological patterns and emphasize the importance of ecology both to humans and to our planet as a whole.

CHAPTER SUMMARY

54.1 What Is Ecology?

- **Ecology** is the scientific investigation of interactions among organisms and between organisms and their physical environment.
- An organism's environment encompasses both **abiotic** (physical and chemical) and **biotic** components (other living organisms).

- The science of ecology generates knowledge about interactions in the natural world.
- In addition to observations of visible phenomena, ecology relies on a diversity of tools, including mathematical models, molecular techniques, and satellite imaging

- **Environmentalism** is the use of ecological knowledge to inform our decisions about the stewardship of natural resources and ecosystems.

54.2 Why Do Climates Vary Geographically?

- Weather refers to atmospheric conditions at a particular place and time. Climate is the average of atmospheric conditions, and the variation in those conditions, found in a particular place over time.
- The solar energy that reaches a given unit of Earth's surface depends primarily on the angle of the sun's rays, which in turn is a function of latitude. Latitudinal variation in air temperature drives atmospheric circulation patterns of precipitation. **See Figures 54.1 and 54.2**
- Global atmospheric circulation patterns are also driven by the Earth's rotation; these wind patterns in turn drive ocean surface currents. **Review Figure 54.3**
- Organisms respond to climatic challenges with physiological, morphological, and behavioral adaptations.

54.3 What Is a Biome?

- A **biome** is an environment that is defined by its climatic and geographic attributes and characterized by ecologically similar organisms, particularly its dominant vegetation. **Review Figure 54.5, ANIMATED TUTORIAL 54.1**
- The distribution of biomes is determined primarily by climate, but other factors, such as soil characteristics and fire, also influence vegetation. Terrestrial biomes include Arctic and alpine tundra, boreal forest, temperate evergreen and temperate deciduous forests, temperate grasslands, hot and cold deserts, chaparral, thorn forest and savanna, tropical deciduous forest, and tropical evergreen forest. **SEE ANIMATED TUTORIAL 54.2**

54.4 What Is a Biogeographic Region?

- **Biogeography** is the scientific study of the patterns of distribution of populations, species, and ecological communities.
- The boundaries of **biogeographic regions** are drawn where assemblages of species change dramatically over short distances. These boundaries generally correspond to present or past barriers to dispersal. **Review Figures 54.7 and 54.8, WEB ACTIVITY 54.1**
- A species that is found only in a certain region is said to be **endemic** to that region.
- The theory of continental drift explains some discontinuous distributions that include multiple biogeographic regions. **Review Figure 54.10**
- Biogeographers can transform phylogenetic trees into **area phylogenies** that show where organisms now live or once lived. **Review Figure 54.11**
- When formerly separated land masses come together, species from both biotas may disperse into the other region, a phenomenon known as **biotic interchange**.
- Both **vicariant events** and dispersal across boundaries generate distinctive patterns of species distributions. **Review Figure 54.13**

54.5 How Is Life Distributed in Aquatic Environments?

- Oceanic **life zones** are determined by the distance from the surface, which in turn influences how much light is available to sustain photosynthetic organisms. **Review Figure 54.14**
- Fresh waters—river basins and lakes—are also divided into life zones according to depth and light penetration.
- Estuaries are bodies of water where salt and fresh water mix. This globally small but crucial life zone supports many unique species.

SELF-QUIZ

- Ecology and environmentalism are
 - synonymous; the terms can be used interchangeably.
 - differentiated by the emphasis placed by ecology on the biotic rather than the abiotic world.
 - differentiated by the lack of utility of ecology in solving world problems.
 - differentiated by the inherent focus of environmentalism on human concerns.
 - both scientific fields of inquiry that generate knowledge about the natural world but use different tools.
- A biome is
 - a large ecological unit defined by its climatic and geographic attributes and characterized by ecologically similar organisms.
 - a large ecological unit defined by its dominant animals.
 - a large ecological unit defined by climate characteristics.
 - a large ecological unit defined by the number of photosynthetic species.
 - a large ecological unit defined by biogeochemical cycles.
- The solar energy that reaches a given unit of Earth's surface depends primarily on
 - the angle of the sun's rays.
 - the moisture content of the air.
 - the amount of cloud cover.
 - the strength of the winds.
 - day length.
- Energy from the sun determines
 - air temperature.
 - air and wind circulation patterns.
 - ocean surface currents.
 - All of the above
 - None of the above
- Biogeography as a science began when
 - European naturalists first traveled the globe and noted patterns in the distributions of organisms.
 - Europeans traveled to the Middle East during the Crusades.
 - phylogenetic methods were developed.
 - the theory of continental drift was accepted.
 - Charles Darwin proposed the theory of natural selection.
- Vicariant events
 - result from organisms dispersing across a barrier.
 - were common in the past but are rare today.
 - divide a species into two or more discontinuous populations.
 - were rare in the past but are common today.
 - caused most of today's discontinuous species ranges.

7. The oceans can be divided into life zones even though they are all connected because
 - a. the rate of photosynthesis is low in the oceans.
 - b. ocean currents keep organisms close to where they were born.
 - c. light penetration, and hence photosynthesis, vary with depth and determine where organisms live.
 - d. trade winds keep warm and cold waters separate.
 - e. continents provide barriers to movement of planktonic life forms.
8. A parsimonious interpretation of a distribution pattern is one that
 - a. requires the smallest number of undocumented vicariant events.
 - b. requires the smallest number of undocumented dispersal events.
 - c. requires the smallest total number of undocumented vicariant plus dispersal events.
 - d. accords with the phylogeny of a lineage.
 - e. accounts for centers of endemism.
9. The only biogeographic region that today is completely isolated from the other regions by water is
 - a. the Madagascan region.
 - b. the Ethiopian region.
 - c. the Neotropical region.
 - d. the Australasian region.
 - e. the Nearctic region.
10. Which of the following characteristics is unique to Arctic tundra?
 - a. Winters are long and cold.
 - b. The soil is underlain by a layer of permafrost.
 - c. Many small mammals hibernate in winter.
 - d. Many of the plants are perennials.
 - e. None of these characteristics apply to Arctic tundra.

FOR DISCUSSION

1. Discussions about the likelihood of life on other planets often focus on their proximity to a sunlike star. How different might life on Earth be if the planet's distance from the sun were considerably greater?
2. Today, by far the greatest number of species of fruit flies (genus *Drosophila*) is found in the Hawaiian Islands. Would you conclude that the genus originally evolved in Hawaii and spread to other regions? Under what circumstances do you think it is safe to conclude that a group of organisms evolved in the same region where the greatest number of species live today? (*Hint*: Review the discussion of equid phylogeny and Figure 54.11.)
3. The desert locust (*Schistocerca gregaria*), which has been a major agricultural pest for millennia, is found throughout the Middle East, western Asia, and Africa. Every other species in the genus *Schistocerca* is found in the Western Hemisphere. How could you determine whether the current distribution of species resulted from eastward dispersal (from North America to Africa) or from westward dispersal (from Africa to the Americas)?
4. Processes in nature do not always conform to the parsimony principle. Why, then, do biogeographers often use the parsimony principle to infer the histories of species and lineages?
5. A well-known legend states that Saint Patrick drove the snakes out of Ireland. Give some alternative explanations, based on biogeographic principles, for the absence of indigenous snakes in that country.
6. Most of the world's flightless birds are either nocturnal and secretive (such as the kiwi of New Zealand) or large, swift, and powerful (such as the ostrich of Africa). The exceptions are found primarily on islands, and many of these island species became extinct when humans (and their domesticated animals) arrived. What conditions on islands might permit the survival of flightless birds? Why has human colonization so often resulted in the extinction of such birds? The power of flight has been lost secondarily in representatives of many groups of birds and insects; what are some possible evolutionary advantages of flightlessness that might offset its obvious disadvantages?

ADDITIONAL INVESTIGATION

Alfred Russel Wallace observed that dramatically different birds inhabited Bali and Lombok, even though the strait that separates them is only 15 miles wide. But most birds can easily fly 15 miles, and can probably see the other island across the water.

What kinds of data, in addition to those gathered by Wallace, could be obtained to determine why birds do not fly across the strait or, if indeed they do cross the water, why they fail to colonize the island on the other side?

Reindeer games

In 1944, in the midst of World War II, the U.S. Coast Guard established a LORAN (Long-Range Aids to Navigation) tracking station on the tiny island of St. Matthew in Alaska, an isolated and otherwise unoccupied patch of tundra more than 300 km from the nearest village. As an emergency food supply for the 19 men assigned to the island, the Coast Guard brought in 29 reindeer (*Rangifer tarandus*) by barge and released them.

The reindeer thrived on the thick, lush mat of lichens that covered the 128-square-mile island. Other than the men, the island had no reindeer predators; its only other animal occupants were Arctic foxes, one species of vole, and a few ground-nesting birds. As the war wound down and the men left the island, the reindeer were left behind in an environment of plentiful food and no natural predators.

In 1957, David Klein, at the time a U.S. Fish and Wildlife biologist, visited St. Matthew with a field assistant;

together they counted more than 1,350 reindeer, most of which appeared fat and healthy. However, they also noticed areas of seriously overgrazed lichen mats. Klein did not return to the island until 1963, when he and three colleagues hitched a ride with a Coast Guard cutter. By that time, there were more than 6,000 reindeer packed in at a density of 47 per square mile. The island was covered with reindeer tracks and droppings, and the animals were distinctly smaller than the ones sighted 6 years earlier.

The winter of 1963–1964 brought punishing storms, record low temperatures, and tremendous snowfalls to St. Matthew Island. In August 1965, Coast Guard personnel reported massive reindeer deaths. Klein and two colleagues arranged a return visit in the summer of 1966, at which time they found the island littered with reindeer skeletons. The scientists could locate only 42 living reindeer, 41 of which were adult females; the lone male appeared to have

deformed antlers. In a remarkably short period, the reindeer population had declined by over 99 percent. Lichens had essentially disappeared from the island, replaced almost entirely by sedges and grasses, on which reindeer cannot subsist. By 1980, the reindeer had entirely disappeared from the island.

Introducing large hoofed mammals to small islands is an inherently risky enterprise, as the experience on St. Matthew graphically illustrates. But

Reindeer Pause Part of the St. Matthew reindeer herd is seen in this photograph taken in 1963, shortly before a particularly severe winter destroyed most of this isolated population. The herd had grown exponentially for almost 40 years since being introduced to the island as a food source for soldiers during World War II.

Predators and Population Cycles Wolves are the principal non-human predators of reindeer, moose, and other large grazing mammals in northern forests and tundra. There were no wolves on St. Matthew Island, a fact largely responsible for the reindeer population's ability to grow exponentially.

such introductions do not always end in disaster. Reindeer populations introduced to the sub-Antarctic island of South Georgia almost a century ago have persisted and appear to be stable.

Why would populations of a particular species in one place explode and crash, but in another seemingly similar place remain stable over time? Understanding how and why populations change in size is more than an academic pursuit. Ecologists study how populations change over time because that knowledge is critical for understanding why some species become pests in some places and not in others, for managing sustainable harvests of economically important species, and for designing plans for conserving endangered species.

IN THIS CHAPTER we will examine how ecologists study populations and investigate how reproductive capacity and environmental resources affect the dynamics of population growth. We will identify factors that limit population densities and determine the effects of environmental variation on population dynamics. Finally, we will show how an understanding of population dynamics is applied to managing populations of importance to humans.

CHAPTER OUTLINE

- 55.1** How Do Ecologists Study Populations?
- 55.2** How Do Environmental Conditions Affect Life Histories?
- 55.3** What Factors Limit Population Densities?
- 55.4** How Does Habitat Variation Affect Population Dynamics?
- 55.5** How Can Populations Be Managed Scientifically?

55.1 How Do Ecologists Study Populations?

Well before ecology became a distinct biological discipline, people engaged in population management. Whenever we grow crops or raise livestock, we are explicitly increasing populations of domesticated plants and animals. Pest control strategies aim to reduce populations of organisms whose presence we consider undesirable. Game wardens, park managers, and conservation biologists aim to maintain stable populations of fish, wildlife, and threatened or endangered species. All of these activities require an understanding of **population dynamics**: the patterns and processes of change in populations. The study of population dynamics also allows us to understand the changes in populations we make inadvertently in the course of other human activities—as when the Coast Guard introduced reindeer to St. Matthew.

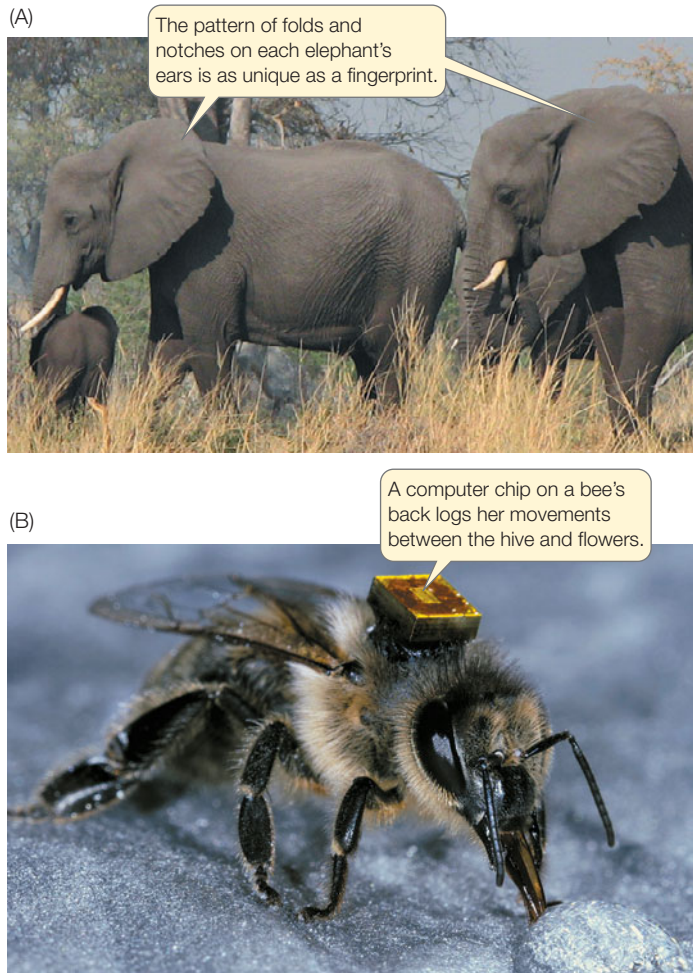

A **population** consists of the individuals of a species that interact with one another within a given area at a particular time. Populations are important units for study because groups of individuals that interact in time and space have ecological characteristics that individuals do not. At any given moment, an individual organism occupies only one point in space and is a particular age and size. The members of a population, however, are distributed over space and vary in age and size.

Population density is the number of individuals per unit of area or volume. Density is a property of all populations and is a function of the processes that add individuals to the population (births and immigration, or movement of individuals into the population) and the processes that reduce the number of individuals in the population (deaths and emigration, or movement of individuals out of the population).

Populations also have a characteristic *age structure*, or distribution of individuals across age categories, and a characteristic *dispersion* pattern, or spatial distribution of individuals in the environment. These characteristics, which are constantly changing due to births, deaths, and movement, influence the stability of populations and affect the ways in which populations of one species interact with populations of other species. Thus, to study populations, ecologists need to count the individuals in a given area, determine their ages, and calculate the rates at which individuals enter and leave the population. The study of these processes is known as **demography**.

Ecologists use a variety of approaches to count and track individuals

How individuals are counted depends on the nature of the organism under study. Populations of animals, for example, can

55.1 Identifying Individuals (A) The pattern of folds and notches on the ears of an elephant is as unique and distinctive as a fingerprint and can be used to recognize individuals in a population. (B) Worker bees in a hive are individually indistinguishable to ecologists, who have come up with ingenious methods of marking. This female honey bee sports a computer chip on her back, which not only identifies her but also logs her movements between the hive and flowers.

be more challenging to count than populations of trees. Most animals can move, so, to avoid double counting, individuals must be identified. Nevertheless, counting every tree in a forest can be logistically difficult, even though the trees are standing still.

In some species, individuals are large and distinct enough, and populations small enough, that investigators can identify all the individuals and count them. Biologists performed this type of count, called a *full census*, on the elephant population of Samburu and Buffalo Springs national reserves in Kenya. By monitoring the population for 21 months, they learned to recognize each of the 760 individual elephants, primarily by their unique and distinctive ear markings (**Figure 55.1A**). Individual recognition is impossible or impractical for most species, however, and to identify such individual organisms they must be marked in some artificial way (**Figure 55.1B**).

In most species, populations are too large and their individual members too small, too similar in appearance, and/or too

mobile for a full census to be conducted. Thus population sizes are often estimated from representative samples using statistical methods.

Population densities can be estimated from samples

Ecologists usually measure the densities of terrestrial organisms as the number of individuals per unit of area; for organisms living in soil, air, or water, the number or mass per unit of volume may be used. Ecologists obtain these measurements from sample units, then extrapolate from these samples to estimate the total population density.

Estimating population densities is easiest for sedentary organisms. Investigators need only count the individuals in a sample of representative locations and extrapolate the counts to the entire geographic range of the population. Individuals may be counted within marked and measured areas called *quadrats*. Plants are often counted along a linear *transect*: a line drawn across the population's range (often designated by a string marked at regular intervals). Any individual that touches the line is counted. By making repeated counts with either of these methods, investigators can make reasonably good estimates of the size of a population.

Counting mobile organisms is more difficult because individuals move into and out of sampling areas. In such cases, investigators may use the **mark-recapture method**. They begin by capturing, marking, and then releasing a number of individuals. Later, after the marked individuals have had time to mix with unmarked individuals in the population, another sample of individuals is captured. The proportion of individuals in the new sample that are marked can be used to estimate the total size of the population in the defined area, as follows:

$$\text{Estimated population size } N = \frac{n_1 \times n_2}{n_{1 \cap 2}}$$

where

n_1 = the total number of individuals in the first sample (captured, marked, and released)

n_2 = the total number of individuals in the second sample

$n_{1 \cap 2}$ = the number of marked individuals recaptured in second sample (the "intersection set" of samples 1 and 2)

In other words, we assume that the proportion of individuals in the second sample that were captured and marked in the first sample is about the same as the proportion of individuals in the sampling area that were captured in the first sample.

Quantifying the size and determining the density of populations are important, but these numbers are only a starting point for understanding population dynamics, because not all individuals contribute equally to population growth.

Populations have age structures and dispersion patterns

The **age structure** of a population—the distribution of individuals across all age groups—has a profound effect on population growth because reproductive capacity varies with age. Populations with a large proportion of young individuals have a

55.2 Changes in Age Structure

Influence Population Growth The elephant population in Kidepo Valley National Park, Uganda, was monitored between 1970 and 2000. During this time, the proportion of the population achieving prime reproductive age range (15–30 years) grew considerably. Such an age structure in a population is likely to result in an increased rate of growth.

greater potential to grow than populations dominated by individuals that are beyond their peak reproductive years.

For some species, reproduction may be the province of only a tiny fraction of the entire population for only a short interval during the life cycle. Adults of the tiny insect *Clunio maritimus* (the “one-hour midge”) mate, lay eggs, and die within about an hour after completing their larval development. In contrast, some vertebrates are capable of reproducing for years. **Figure 55.2** shows the results of a long-term study of the age structure of the elephant population in Kidepo Valley National Park, Uganda. Relative to 1970, the 2000 population skewed significantly toward females, particularly those over 25 years of age. These two disparate age structures were the result of years of differential mortality among young elephants due to drought, and of increased male death rates due to ivory poachers. The age structure as of 2000 portends an increase in the population’s growth rate, given that female African elephants become fertile around age 10–15 and can continue producing offspring through their fifties.

Dispersion refers to the distribution of individuals in space within a population. Dispersion determines patterns of interaction among individuals and can thus have important effects on population growth. In addition, ecologists must understand the dispersion patterns of a species to choose appropriate sampling areas and methods for estimating population sizes.

Ecologists recognize three basic dispersion patterns (**Figure 55.3**):

- A *clumped* dispersion pattern occurs when the presence of one individual at any point in space increases the probability of others being near that point.
- A *regular* dispersion pattern occurs when the presence of one individual at any point in space reduces the probability of others being near that point.
- A *random* dispersion pattern occurs when there is an equal probability of an individual occupying any point in space.

(A) Clumped dispersion

(B) Regular dispersion

(C) Random dispersion

55.3 Dispersion Patterns (A) Orcas hunting in pods display a clumped dispersion pattern. (B) Nesting seabirds often stake out territories with a radius defined by their wingspans—an amount of space they can defend without leaving the nest. This results in even dispersion. (C) Dandelion seeds are dispersed by the wind in random fashion.

Spatial variation in environmental conditions strongly influences dispersion patterns. Small-scale differences in temperature, humidity, or wind speed can make particular places more or less suitable for certain organisms. Aphids, for example, cluster along the protruding veins of leaves, where they are sheltered from wind. Interactions among individuals may also bring about characteristic dispersion patterns. Social life, with the cooperation it involves, tends to promote clumped dispersion patterns, as seen in Figure 55.3A. Intraspecific competition for food, space, or mates, on the other hand, tends to space individuals apart in regular dispersion patterns (Figure 55.3B).

Changes in population size can be estimated from repeated density measurements

Ecologists can use multiple estimates of population densities made over time to estimate the rate at which a population is growing or decreasing. Over any given interval of time, the number of individuals in a population increases by the number of individuals added to the population by birth and immigration and decreases by the number of individuals lost from the population by death and emigration. This relationship is expressed mathematically in the equation

$$N_1 = N_0 + (B - D) + (I - E)$$

where

N_1 = the number of individuals at time 1

N_0 = the number of individuals at time 0

B = the number of individuals born between time 0 and time 1

D = the number that died between time 0 and time 1

I = the number that immigrated between time 0 and time 1

E = the number that emigrated between time 0 and time 1

Using this equation to estimate N_1 over multiple time intervals helps researchers estimate changes in population density.

Life tables track demographic events

The study of population dynamics requires keeping track of *demographic events* (births, deaths, immigration, and emigration) in populations and determining the *rate* (number per unit of time) at which they occur. A **life table** is a tool that ecologists use for these purposes. Life insurance companies use similar tables (called “actuarial tables”) to determine how much to charge people of different ages for insurance policies. Data from life tables can be used to identify the principal *mortality factors*, or causes of death, at particular life stages, to predict future population trends, and to develop strategies for managing populations of species of commercial or ecological value.

COHORT LIFE TABLES Life tables can be constructed by a number of methods. To construct a *cohort life table*, investigators start with a **cohort**—a group of individuals born within the same time frame, or *age class*—and record their deaths until no individuals from the cohort remain alive. This type of life table is sometimes called a *horizontal life table* because it is based on data collected across the life span.

TABLE 55.1

Life Table for the 1978 Cohort of Cactus Ground Finch (*G. scandens*) on Isla Daphne

AGE CLASS (YEARS)	NUMBER ALIVE	SURVIVORSHIP ^a (l_x)	MORTALITY ^b
0–1	210	—	0.57
1–2	91	0.43	0.14
2–3	78	0.37	0.10
3–4	70	0.33	0.07
4–5	65	0.31	0.05
5–6	62	0.30	0.32
6–7	42	0.20	0.45
7–8	23	0.11	0.35
8–9	15	0.07	0.07
9–10	14	0.07	0.21
10–11	11	0.05	0.09
11–12	10	0.05	0.60
12–13	4	0.02	0.25
13	3	0.01	—

^aSurvivorship = the proportion of the original cohort (here, of 210 individuals) who survive to age x .

^bMortality (“death rate”) = the proportion of individuals of age x who die before reaching age $x + 1$.

The age categories used in a cohort life table depend on the life cycle of the organism of interest. *Age-dependent life tables* track demographic events as a function of calendar age. *Stage-dependent life tables* track demographic events at various stages of the life cycle (e.g., eggs, larvae, pupae, and adults in insects). They are commonly used when survival and reproduction depend more on developmental stage than on calendar age, as is the case, for example, with insects and other animals that undergo metamorphosis.

Using the data in a cohort life table, investigators can calculate **mortality**: the proportion of individuals of each age class that die before reaching the next age class. They can also calculate **survivorship** (represented by the term l_x), which is the likelihood of an individual member of the cohort surviving to reach age x (Table 55.1).

ESTIMATING REPRODUCTIVE CAPACITY A cohort life table can also be used to track the degree to which individuals in different age categories contribute to reproduction (and hence population growth). Because only females produce offspring, life tables generally track the number of offspring produced by each female during each time period—a factor called **fecundity** (indicated in a life table by the term m_x). The portion of the life table that tracks fecundity is called a *fecundity schedule* (Table 55.2). Such data allows conservation biologists and other scientists to estimate a population’s potential for growth (see Chapter 59).

The data shown in Tables 55.1 and 55.2 track the survivorship (l_x) and fecundity (m_x), respectively, of a cohort of cactus ground finches (*Geospiza scandens*) on Isla Daphne in the Galá-

TABLE 55.2

Fecundity Schedule for the 90 Females of the 1978 Cohort of Cactus Ground Finch (Table 55.1)

AGE CLASS (YEARS)	FECUNDITY ^a (m_x)

7–8	0.00
8–9	0.00
9–10	2.20
10–11	0.00
11–12	0.00

^a Fecundity = number of fledglings per female per breeding season.

pagos archipelago. Peter and Rosemary Grant followed a cohort of 210 birds from 1978, when they hatched, until 1991, when only 3 individuals—all males—remained alive. All of the cactus ground finches on the island were banded so that the Grants could recognize them as individuals.

The *G. scandens* life tables show that mortality was high during the first year of life, then dropped dramatically for several years before increasing in later years. The fecundity data indicate that females of all ages breed, and breeding success does not correlate exclusively with age. Other observations of conditions on Isla Daphne revealed a correlation with rainfall, which in the Galápagos varies dramatically from year to year (see Table 55.2). These life tables and other ecological data, taken together, suggest that the survival of adult birds and the number of offspring they are able to fledge depend on food availability—that is, on cactus flower and fruit production, which are strongly correlated with rainfall. In short, life table data can be useful in separating out the many ecological factors that affect population dynamics.

Fecundity schedules vary greatly among species not only because organisms differ in the number of offspring they can produce, but also because they vary in the timing of reproduction. Female cactus ground finches begin breeding at the age of 1 or 2 years and, in favorable conditions, can fledge multiple offspring each breeding season. In contrast, female African elephants do not produce offspring until they are at least 15 years old and usually produce only one calf about every 5 years.

VERTICAL LIFE TABLES Because not all species can be easily followed through time, some life tables are constructed by sampling a population at a single time. These life tables cut across all age categories and thus are known as *vertical life tables*. One way to construct a vertical life table is to record information from a *death assemblage*, a collection of bodies or fossils of indi-

viduals that lived together in a particular place at a given time. The birth and death dates on tombstones in a cemetery, for example, can be used to construct a vertical life table for a human population and to estimate its probability of reaching different ages. A 1944 study of Dall mountain sheep (*Ovis dalli dalli*) in Mt. McKinley (now Denali) National Park, Alaska, was based on 608 sheep skulls collected throughout the park. Age at death was estimated by counting growth rings on the horns.

SURVIVORSHIP CURVES The construction of life tables has allowed ecologists to observe common patterns, reflecting common solutions to ecological challenges, across a tremendous diversity of organisms. For example, mortality data from a life table can be used to plot a **survivorship curve**. Survivorship curves are correlated with general patterns of life history traits, which in turn suggest the mortality factors the population faces in its environment. Ecologists classify survivorship curves into three types (**Figure 55.4A**):

- *Type I*, or physiological, survivorship curves are typical of organisms that experience high overall survivorship through adulthood (such as humans and many other large mammals). Parental care and low fecundity are typical of species with this type of survivorship curve.
- *Type II*, or ecological, survivorship curves are typical of organisms faced with a constant risk of mortality at all ages (such as most birds).
- *Type III*, or maturational, survivorship curves are typical of organisms that experience low juvenile survivorship (such as most insects and annual plants). Species with this type of survivorship curve tend to produce many offspring, but provide little or no parental care.

Note that survivorship curves can differ even among close relatives within a taxonomic group (**Figure 55.4B**).

55.1 RECAP

To understand the dynamics of populations, ecologists measure population density, age structure, and dispersion patterns. Life tables can be constructed either by following a cohort of individuals through time or by recording age at death in a vertical life table.

- What are some of the ways in which population density can be measured? **See p. 1169**
- What kinds of information do life tables provide about a population? **See pp. 1171–1172 and Tables 55.1, 55.2**
- Describe the three types of survivorship curves. **See p. 1171 and Figure 55.4**

Survivorship and fecundity are attributes of all populations, but even within species, environmental variation across a species’

55.4 Survivorship Curves (A) Ecologists recognize three types of survivorship curves. (B) Even species that are closely related may have survivorship curves of different types, as indicated here by the survivorship curves of three species of lizards.

range influences these measures. Comparisons across populations and species reveal different patterns in life history traits, which allow organisms to cope with different environmental challenges.

55.2 How Do Environmental Conditions Affect Life Histories?

The way in which an organism partitions its time and energy among growth, maintenance, and reproduction is called its **life history strategy**. Because resources and mortality factors vary greatly among environments, life history strategies also vary dramatically. Those variations, in turn, determine how fast populations can grow.

Survivorship and fecundity determine a population's intrinsic rate of increase

To see how a population is likely to grow, ecologists can use life table data to calculate the population's per capita growth rate, also known as the **intrinsic rate of increase**, symbolized as r . A population's intrinsic rate of increase is the difference between the birth rate (b) and the death rate (d) per individual (*per capita*) (leaving aside, for the moment, immigration and emigration). It is expressed by the equation

$$r = b - d$$

If the birth rate is greater than the death rate, then $r > 0$, and the population is growing. If the death rate is greater than the birth

rate, then $r < 0$, and the population is declining. The equilibrium state $r = 0$ would indicate a stable population that is neither growing nor declining significantly. When applied to the human population, it is sometimes referred to as "zero population growth," with implications we will see in Section 55.5.

Life history traits vary with environmental conditions

Both survivorship (l_x) and fecundity (m_x) are highly habitat-dependent in practice, and the intrinsic rate of increase can thus change as the environment changes. The life history traits most influenced by environmental conditions include:

- age at first reproduction (generation time)
- number of broods per female (the number of times a female produces offspring)
- number of offspring per brood (the number of offspring produced each time a female reproduces)

These factors vary not only between species, but also between populations within species.

Opportunities for reproduction for some species are limited to certain locales or certain times of year, whereas other species and populations can breed continuously over their life span. Many desert wildflowers grow and flower only during the spring rainy season, and they may not be able to reproduce at all in years when rainfall is inadequate. In contrast, some tropical vines are able to flower continuously in their warm, moist rainforest environment.

Species that can reproduce multiple times over the course of their adult lives are **iteroparous** (*itero*, to repeat; *pario*, to beget). **Semelparous** species (*semel*, once), on the other hand, reproduce only once in their lives (Figure 55.5). Generally, semelparous species produce many more offspring in their single brood than iteroparous species do over their lifetime; semelparity is thus sometimes called "big bang" reproduction.

Orgyia antiqua

55.5 Big Bang Reproduction Semelparous species reproduce only once and invest a great deal of energy in producing the maximum number of offspring. Female rusty tussock moths do not fly but remain with their empty cocoons, which are attached to the plants that are the caterpillar-stage food source. The stationary female lays a large number of eggs and then dies. When the eggs hatch the following spring, the larvae are surrounded by foliage they can eat.

Semelparity is typical of organisms that experience no great survival advantage upon reaching adulthood, including some fishes, many insects, and all annual plants (i.e., organisms with a type III survivorship curve). In contrast, iteroparity is typical of organisms whose survival chances increase once they reach maturity (those with a type I or II survivorship curve). For example, because environmental conditions within the nests of social insects (such as honey bees and ants) are remarkably stable, iteroparity is the rule; some queens may live 10 years or longer and reproduce over their entire adult lives.

Life history traits are influenced by interspecific interactions

Predation and other interactions among species can influence life history strategies in many ways. Some populations of guppies (*Poecilia reticulata*) in Trinidad, for example, live in streams where they are attacked and eaten by larger fish. But some streams have waterfalls that predatory fishes are unable to negotiate. Guppies that live in the predator-free areas upstream from those waterfalls have lower death rates than guppies below the falls. To see whether the risk of being eaten by a predator influenced the life history strategies of these guppies, David Reznick and his colleagues collected guppies from high-preda-

tion and low-predation sites and raised them in the laboratory. Some guppies from each group were provided with plentiful food, and others with limited food, to simulate the variation the fish would typically encounter in their home streams. In the laboratory, where no predators were present, guppies from high-predation sites matured earlier, reproduced more frequently, and produced more offspring in each brood than guppies from low-predation sites, no matter how much food they received. The investigators concluded that predation had selected for early and frequent reproduction.

55.2 RECAP

The difference between birth rate and death rate provides an estimate of a population's intrinsic rate of increase, or r . That rate is strongly influenced by the population's life history strategy, which in turn is highly dependent on ecological conditions.

- What life history traits vary with environmental conditions? **See p. 1173**
- Explain the difference between iteroparity and semelparity. **See p. 1173**
- How can predation affect the evolution of life history strategies? **See p. 1174**

A species may be rare in one location, yet elsewhere within its range it may be superabundant. A species that is rare in one locality one year may be abundant the next year. For any given species, environmental factors limit the growth of its populations in different places and at different times. Population ecologists work to identify and understand these factors.

55.3 What Factors Limit Population Densities?

What would happen if all the offspring produced by a population survived to reproduce themselves? The prospects are alarming. In 1911, L. O. Howard, then chief entomologist of the U.S. Department of Agriculture, estimated that a pair of flies beginning to reproduce in Washington, D.C., on April 15 could produce a population of 5,598,720,000,000 adults by September 10. Other entomologists took issue with Howard's calculation—they pegged the number much *higher*. Given such amazing reproductive capacities, it is clear there are forces at work that limit the growth of fly populations (and populations of every other organism).

All populations have the potential for exponential growth

As the number of individuals in a population increases, the number of new individuals added per unit of time accelerates, even if the intrinsic rate of increase remains constant. If births and deaths occur continuously and at constant rates, a graph of

(A) Elephant seals, Año Nuevo Island

(B) Reindeer, St. Matthew Island

**55.6 Exponential Population Growth Can Lead to a Population Crash**

(A) Abundant resources allow a population to grow exponentially, as did the elephant seal population on Año Nuevo Island, California. (B) The reindeer herd introduced on St. Matthew Island grew exponentially for many years despite a decreasing food supply. A single catastrophically cold winter triggered a population crash that eventually resulted in the death of the entire island reindeer population.

—yourBioPortal.com—

GO TO Animated Tutorial 55.1 • Exponential Population Growth

the population size over time forms a continuous upward curve (Figure 55.6A). This pattern, known as **exponential growth**, can be expressed as

$$\frac{\text{change in number of individuals}}{\text{change in time}} = b - d$$

$$\frac{dN}{dt} = b - d$$

Using the notation of differential calculus, which is better suited to short time intervals, this equation can be expressed as

$$\frac{dN}{dt} = (b - d)N$$

Because the intrinsic rate of increase, r , is equivalent to $b - d$, the **equation for exponential growth** can be simplified to

$$\frac{dN}{dt} = rN$$

The term dN/dt is the rate of change in the size of the population over time, and the expression rN is sometimes called the **biotic potential** of the population.

For very short periods, some populations may grow at rates close to their biotic potential. During the 20 years following their introduction, the reindeer population on St. Matthew, described at the opening of this chapter, grew exponentially. When the reindeer herd was introduced to the island, it had ample habitat, abundant food, and no predators, so there was nothing to

limit the population's growth. Favorable climatic conditions also allowed the population to grow exponentially. A rapid change in those conditions—deep snow during one particularly cold winter—was a major factor leading to the population's crash (Figure 55.6B).

Logistic growth occurs as a population approaches its carrying capacity

No real population can maintain exponential growth for very long. As a population increases in density, the resources it requires—such as food, nest sites, or shelter—become depleted. In the absence of adequate resources to sustain more individuals, birth rates drop and death rates rise.

Any given environment has only enough resources to support a finite number of individuals of a species indefinitely. That number of individuals, referred to as the environment's **carrying capacity (K)**, is a function of its resources. The growth of a population typically slows down as its density approaches the environmental carrying capacity. A population that exhibits decreasing growth as resources become limiting will display a pattern called **logistic growth**, in which a graph of the population size over time forms an S-shaped curve. Figure 55.7 shows this growth pattern in a laboratory population of beetles that was maintained on a constant food supply.

An S-shaped curve can be generated from the equation for exponential growth (left) by adding a term that slows the population's growth as it approaches carrying capacity:

$$K - \frac{N}{K}$$

The above term represents the *reduction in population growth caused by preemption of available resources* and is referred to as *environmental resistance*. As long as population size is less than carrying capacity (i.e., $N < K$), only a fraction of the available resources are being used. As the population approaches carrying capacity, however, the fraction of resources available for any new

55.7 Logistic Population Growth Levels Off In an environment with limited resources, a population typically stops growing exponentially before it reaches the environmental carrying capacity (K). The data here was recorded from a laboratory population of sawtoothed grain beetles maintained on a constant food supply; it is a typical logistic growth pattern, which forms an S-shaped curve.

—yourBioPortal.com—

GO TO Web Activity 55.1 and Animated Tutorial 55.2 • Logistic Population Growth

individual becomes smaller. The implication is that each individual added to the population depresses population growth by an equal amount. Thus,

$$\frac{\text{rate of change in population size over time}}{\text{size over time}} = \text{biotic potential} \times \text{environmental resistance}$$

or, in mathematical terms,

$$\frac{dN}{dt} = rN \frac{K - N}{K}$$

Population growth stops when $N = K$ because at that point, $K - N = 0$, so $(K - N)/K = 0$, and thus $dN/dt = 0$.

Population growth can be limited by density-dependent or density-independent factors

When resources are limited, adding more individuals to a population runs the risk of making things worse for everyone. Factors with an effect on population size that increases in proportion to population density are called **density-dependent** regulation factors. These include:

- **Food supply.** As a population increases, it may deplete its food supply, reducing the amount of food available to each individual. Poor nutrition may then increase the death rate and/or decrease the birth rate.
- **Predators** may be attracted to areas with high densities of their prey. If predators capture a larger proportion of the prey population than they did when that population was small, the death rate of the prey population rises.
- **Pathogens** spread more easily in dense populations than in populations with fewer individuals per unit of area, resulting in a rise in the death rate.

Not all population regulation factors act in a density-dependent manner. A period of extreme cold or a hurricane that blows down most of the trees in its path may kill a large proportion of the individuals in a population regardless of its density, and thus are said to be **density-independent**. Abiotic factors (such as extreme temperatures) tend to act on populations in a density-independent manner, whereas biotic factors (such as competition for food) tend to be density-dependent.

Different population regulation factors lead to different life histories

Species vary in their capacity to reproduce, as well as in the extent to which they are vulnerable to density-dependent and density-independent mortality factors. Some of this variation in life history traits appears to result from adaptation to different habitat conditions. Generally, unpredictable habitats are associated with high fecundity and correspondingly high r , as organisms make the most of rare opportunities to reproduce; conversely, predictable habitats, where organisms have a high probability of reproductive success, are associated with low fecundity and low r .

Species whose life history strategies allow for high intrinsic rates of increase are called **r -strategists**, and species whose life history strategies allow them to persist at or near the carrying capacity (K) of their environment are called **K -strategists** (Figure 55.8). Many species display elements of both strategies.

For r -strategists, life is uncertain. Individuals tend to reproduce only once and to produce large numbers of offspring. They can generally tolerate a wide range of resource conditions. K -strategists are adapted to predictable environments, are long-lived, and reproduce several times; their smaller numbers of offspring have a high probability of surviving to adulthood. K -strategists tend to be more specialized in their resource use and less tolerant of variation in resource quality. That life history strategies can evolve is suggested by genetic correlations among suites of life history traits. Such genetic correlations imply either simultaneous selection on two life history traits or linkages among the genes that code for those traits. Across *Drosophila melanogaster* strains, for example, intrinsic rate of increase is positively correlated with the ability to reproduce under starvation conditions and with the ability to develop on a variety of media in the laboratory—both of which are consistent with the r strategy of tolerating a wide range of conditions.

Several factors explain why some species achieve higher population densities than others

Density-dependent and density-independent factors can explain how populations grow or decline, but they do not explain why some species are common whereas others are rare—that is, why the characteristic densities of species differ. Many factors explain why typical population densities vary so greatly among species, but four of them are especially influential:

- *Species that use abundant resources generally reach higher population densities than species that use scarce resources.* Thus, on average, the fruit fly *Drosophila melanogaster*, which feeds on

r-strategists**K-strategists****55.8 Two Life History**

Strategies Species whose life histories are geared to achieve the maximum possible rate of population increase are referred to as *r*-strategists; those whose population dynamics are bounded by carrying capacity are *K*-strategists. The life histories of most species combine elements of both types.

HABITAT
Can inhabit a broad range of habitats. High tolerance for both environmental instability and low-quality resources.

PHYSIOLOGY
Rapid embryonic development, rapid maturation to reproductive age, small body size.

REPRODUCTIVE STRATEGY
Random mating. Reproduce once (semelparity) resulting in a large number of offspring. Little or no parental investment in each offspring.

SURVIVORSHIP
Short life span, density-independent mortality, typically a Type 3 survivorship curve (see Figure 55.4).

POPULATION FLUCTUATION
Short periods of exponential population growth (*r*) followed by periodic or seasonal population crashes.

EXAMPLES
Dandelions, house flies, rabbits

HABITAT
Specific habitat requirements, including environmental stability. Efficient users of specific and usually high-quality resources.

PHYSIOLOGY
Extended embryonic development, long maturation to reproductive age, large body size.

REPRODUCTIVE STRATEGY
Mate choice, pair bonds. Reproduce many times (iteroparity), each event producing few offspring. Large parental investment in each offspring.

SURVIVORSHIP
Long life span, density-dependent mortality, typically a Type 1 or 2 survivorship curve (see Figure 55.4).

POPULATION FLUCTUATION
Slowly rising population growth that stabilizes and levels off at carrying capacity (*K*).

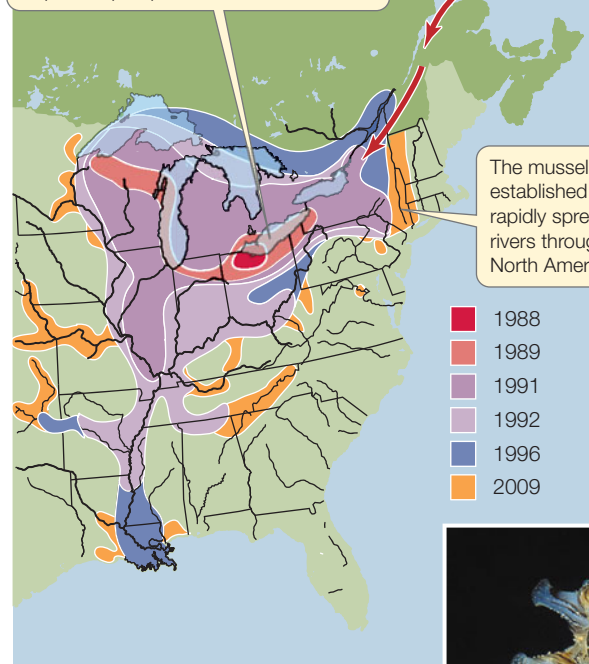

EXAMPLES
Oak trees, bluebirds, polar bears

yeasts and other microbes found on just about any kind of rotten fruit, reaches substantially higher population densities than do other fruit fly species that feed on the microbes found on specific fruits.

- *Species with small body sizes generally reach higher population densities than species with large body sizes.* In general, population density decreases as body size increases because, on a per capita basis, small individuals require less energy to survive than large individuals.
- *Complex social organization may facilitate high population densities.* Highly social species, including ants, termites, and humans, can achieve remarkably high population densities.
- *Some newly introduced species reach high population densities.* Species that are introduced into a new region, where their normal predators and pathogens are absent, sometimes reach population densities much higher than those in their native ranges. Sometimes these high population densities are only temporary; these densities decline if and when new mortality factors exert an influence. However, in many cases, in the absence of such factors, populations in the newly colonized habitat remain so dense that the introduced species becomes a major problem for native species.

The population of zebra mussels (*Dreissena polymorpha*) in North America demonstrates the speed with which newly introduced populations can grow. Zebra mussels first appeared in Lake St. Clair, between Lake Erie and Lake Huron, in 1988. They were probably transported there from their native Europe in the ballast water of transoceanic cargo ships. They spread rapidly and today occupy most of the Great Lakes and the Mississippi River drainage (**Figure 55.9**), reaching densities as high as 400,000 individuals per square meter in some places. Because they attach to any stable un-

Zebra mussels entered North American waters when ballast water from European ships was pumped into Lake Erie.

The mussels became established and rapidly spread via rivers through eastern North America.

55.9 Newly Introduced Populations

Can Grow Rapidly Between 1989 and 2005, the range of zebra mussels in eastern North America increased exponentially. Humans can unwittingly transport zebra mussel larvae from one body of water to another in their fishing boats and other watercraft, and in recent years the invasive pest has begun to appear in lakes and streams of the American West.

Dreissena polymorpha

derwater substratum, zebra mussels can cover the bottoms of boats and docks and clog municipal water supply intakes and power plant pipelines. They even settle on other aquatic organisms, causing problems for native mussels. Such high densities are never found in their native Europe, where over 100 species of predators and parasites keep their population densities under control.

Evolutionary history may explain species abundances

The four key factors that explain variation in population densities, as important as they are, cannot explain all differences in species abundances. For example, although Douglas firs and giant sequoias are both large trees that use the same sources of energy (sunlight) and nutrients, Douglas firs are widespread and abundant in western North America, whereas giant sequoias are restricted to a few groves in southern California. Similarly, each of several species of desert pupfish is restricted to a single spring in Death Valley, California, whereas smallmouth bass live in most of the rivers and lakes in eastern North America. To explain these differences, it is important to know not just the contemporary ecology of these organisms, but also their long-term evolutionary history.

As Section 23.2 describes, a new species can originate in several ways. Species that arise by polyploidy or by founder events inevitably begin with a very small, local population. Desert pupfish species appear to have evolved in isolation as increasing aridity in Death Valley over the past 50,000 years cut once continuous populations off from one another. Conversely, when a species is declining toward extinction (as may be happening to the giant sequoia), its range shrinks until it vanishes when the last individual dies.

55.3 RECAP

Population sizes are limited by the carrying capacity of the environment, which is determined by the availability of resources as well as by biotic interactions. Species associated with unpredictable habitats tend to be *r*-strategists, and species associated with predictable habitats tend to be *K*-strategists.

- Why can populations grow exponentially only for short periods? [See p. 1175 and Figures 55.6 and 55.7](#)
- What is the difference between density-dependent and density-independent factors? [See p. 1176](#)
- Describe the characteristics of *r*-strategists and *K*-strategists. [See p. 1176 and Figure 55.8](#)

All species, no matter how abundant, are found only in those habitats in which they can survive and reproduce well enough to persist over time. Yet a species is rarely found in all of the habitats that seem suitable for it. The evolutionary histories of species supply one explanation for this observation. The next section explores another explanation: spatial variation in habitat suitability.

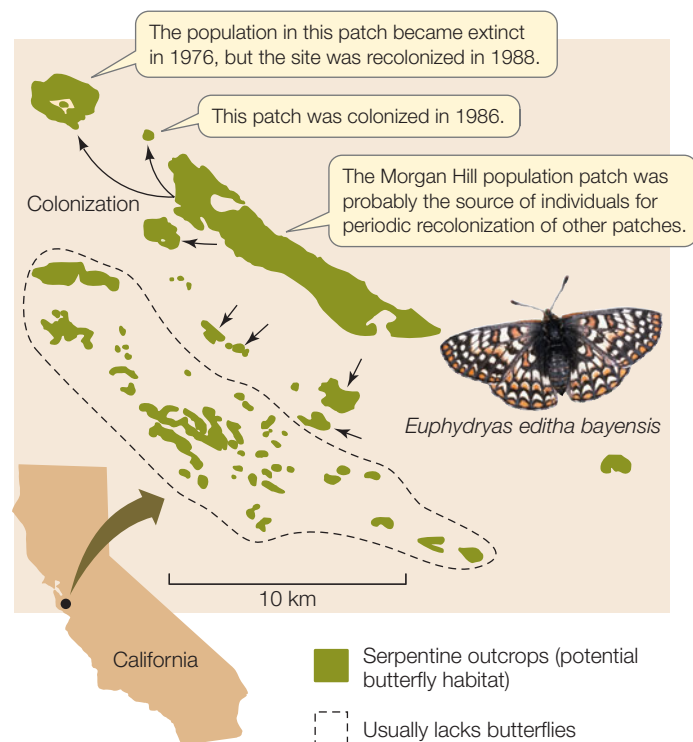

55.4 How Does Habitat Variation Affect Population Dynamics?

Most natural history field guides display maps that show the geographic range over which a species is found. But no species, not even the most abundant, is found everywhere within its mapped range. Every species has particular habitat requirements that determine where within its range it will occur.

Many populations live in separated habitat patches

Most organisms live in distinct **habitat patches**: areas of a particular habitat type that are surrounded by other, less suitable habitats. Some populations living in separated habitat patches are effectively divided into separate, discrete *subpopulations*, linked together by regular movement of individuals between patches. The larger population to which such subpopulations belong is known as a **metapopulation**.

Each subpopulation has a probability of “birth” (colonization of its habitat patch) and “death” (extinction in that patch). Each subpopulation grows in the ways we have described, but because the subpopulations are much smaller than the metapopulation, local disturbances and random fluctuations in numbers of individuals are more likely to cause the extinction of a subpopulation than of the entire metapopulation. However, if individuals move frequently between subpopulations, immigration may prevent declining subpopulations from becoming extinct, a process called the **rescue effect**.

55.10 A Checkerboard of Checkerspots The Bay checkerspot butterfly metapopulation is divided into a number of subpopulations confined to patches of habitat (serpentine rock outcrops) that contain its food plants.

The Bay checkerspot butterfly (*Euphydryas editha bayensis*) provides a dramatic illustration of the dynamics of metapopulations. The caterpillars of this butterfly feed on only two species of annual plants, California plantain and purple owl's clover, which are restricted to outcrops of serpentine rock on hills south of San Francisco, California. In 1960, Paul Ehrlich and his colleagues at Stanford University began studying a population of this butterfly in the Jasper Ridge Biological Preserve near the Stanford campus. They determined that the Jasper Ridge population was actually a subpopulation within a large, very fragmented metapopulation. They found that, over the years, three subpopulations within this metapopulation varied enormously and asynchronously in size. Larval survival depends on climatic factors, particularly temperature, the timing of rainfall, and host plant survival. During drought years, most host plants die early in spring, before the caterpillars have developed enough to enter their summer resting stage.

At least three butterfly subpopulations went extinct during a severe drought in 1975–1977. One of the empty patches was repopulated a few years later, most likely by individuals from the largest single subpopulation, near Morgan Hill, which as late as 1989 contained several hundred thousand butterflies (Figure 55.10). In 1998, however, the Morgan Hill subpopulation went extinct. Ehrlich and colleagues examined 70 years of climate data for the region and concluded that increasing climatic variation accounted for the extinction. Without a stable source subpopulation to provide emigrants for recolonization, it is likely that none of the other subpopulations will persist without human intervention.

Corridors allow subpopulations to persist

In any metapopulation, connections between patches, known as **corridors**, play a critical role in facilitating dispersal to maintain subpopulations. Studying corridors is experimentally daunting because long distances may separate patches; moreover, movements of animals, particularly those that fly, can be difficult to monitor. Therefore, to test the importance of corridors, ecologists conducted a small-scale, manipulative experiment using mosses growing on rocks, which provide habitat for a number of small arthropod species, including springtails (minute wingless hexapods) and mites.

—yourBioPortal.com

GO TO Animated Tutorial 55.3 • Habitat Fragmentation

In one experiment, the investigators created patches of habitat by clearing away the mosses surrounding the patches (Figure 55.11). In small, completely isolated patches, the number of small arthropod species present declined about 40 percent within a year. The investigators also created patches that were connected by narrow corridors of moss. In some cases the corridors were left intact; in others, “pseudocorridors” were disrupted by a barrier 10 mm wide. A 10-mm barrier may seem small, but it presents a daunting obstacle to arthropods only 2 mm wide. Six months later, patches connected by unbroken corridors contained more small arthropod species than did patches connected by the disrupted pseudocorridors.

INVESTIGATING LIFE

55.11 Corridors Can Affect Metapopulations

The manipulative experiments summarized here suggest that corridors between patches of fragmented habitat increase the chances of recolonization and thus subpopulation persistence.

HYPOTHESIS Subpopulations of a fragmented metapopulation are more likely to persist if there is no barrier to recolonization.

METHOD

1. Determine the number of species of small organisms (mostly arthropods) living in an established habitat of mosses growing on a large rock.
2. Fragment the habitat by trimming the mosses into patches of various configurations, leaving bare rock surrounding the patches.

3. After 6 months, determine the number of species present in the various patch configurations.

RESULTS

CONCLUSION Even small barriers to recolonization reduce the number of subpopulations persisting in a fragmented habitat.

FURTHER INVESTIGATION: These studies involved the dispersal of very small organisms over very short distances over a very short span of time. How might the longer term effects of imposing barriers to dispersal be investigated?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

55.4 RECAP

A metapopulation consists of separate subpopulations living in distinct habitat patches, among which individuals move regularly by means of corridors.

- What effects do patches of unsuitable habitat have on population structure? **See p. 1178 and Figure 55.10**
- What effects do corridors between habitat patches have on subpopulations? **See p. 1179 and Figure 55.11**

For many centuries, people have tried to reduce populations of species they consider undesirable and maintain or increase populations of desirable or useful species. Such efforts to manage populations are more likely to be successful if they are based on knowledge of how those populations grow and what determines their densities.

55.5 How Can Populations Be Managed Scientifically?

If we wish to increase or decrease populations of other species, we need to understand the life histories and the population dynamics of the organisms we wish to manage. The principles of population dynamics can also help us understand the effects our own population and its activities are having on other species.

Population management plans must take life history strategies into account

Knowing the life history strategy of a species can be helpful in managing populations of commercial value. The black rockfish (*Sebastes melanops*), an important game fish that lives off the Pacific coast of North America, provides one such example. Rockfish have an indeterminate growth pattern—they continue to grow throughout their lives. As in many other animals, the number of eggs a female produces is proportional to her size, so larger females can produce more eggs than smaller females. In addition, older, larger females are better able to provision the eggs they produce with oil droplets, which provide energy to the newly hatched larvae, giving them a head start in life (**Figure 55.12**). Larvae from eggs with larger oil droplets, produced by larger females, grow faster and survive better than do larvae from eggs with smaller oil droplets.

These life history traits have important implications for the management of rockfish populations. Because fishermen prefer to catch big fish, intensive fishing off the Oregon coast from

1996 to 1999 reduced the average age of female rockfish from 9.5 to 6.5 years. Thus the females reproducing in 1999 were, on average, smaller than the females reproducing in 1996. This change decreased the average number of eggs produced by females and reduced the average growth rate of larvae by about 50 percent. Maintaining productive populations of rockfish may require setting aside no-fishing zones where some females can be protected from fishing and allowed to grow to large sizes.

Population management plans must be guided by the principles of population dynamics

If we look at a logistic growth curve (see Figure 55.7), we can see that the number of births tends to be highest when a population is well below its carrying capacity. Therefore, if we wish to maximize the number of individuals that can be harvested from a population, we should manage the population so that it is far enough below the carrying capacity to have a high birth rate. Hunting and fishing regulations are established with this objective in mind.

Populations that have high reproductive capacities can persist even if harvest rates are high. In such populations (which include many fish species), each female may produce thousands or millions of eggs. In many of these fast-reproducing populations, the growth rates of individuals are density-dependent. Therefore, if prereproductive individuals are harvested at a high rate, the remaining individuals may grow faster. Some fish populations can be harvested heavily on a sustained basis because a relatively small number of females can produce sufficient numbers of eggs to maintain the population.

(A) *Sebastes melanops*

(B)

Oil droplet

55.12 Energy Stocks Give Rockfish a Head Start (A) Among black rockfish, older, larger females are more reproductively successful, producing both more eggs and eggs with larger nutritive oil droplets. (B) The oil droplet attached to this rockfish larva provides it with nutrition to fuel its growth until it can feed on its own.

55.13 Overharvesting Can Reduce Fish Populations Populations of cod and haddock on Georges Bank have crashed due to overfishing.

Fish can, of course, be overharvested, as illustrated by the story of the black rockfish. Many fish populations have been greatly reduced because so many individuals were harvested that the few surviving reproductive adults could not maintain the population. Georges Bank, off the coast of New England—a source of cod, haddock, and other prime food fishes—was exploited so heavily during the twentieth century that many fish stocks have been reduced to levels insufficient to support a commercial fishery (Figure 55.13). The haddock population has rebounded enough to support a fishery because commercial fishing of that species ceased and was restarted only after the population had recovered. In contrast, managers reduced fishing pressure on cod only slowly, and the cod population has failed to increase.

Many rapidly reproducing species can recover if overharvesting is stopped, but recovery is more difficult for slowly reproducing species. Twentieth-century whalers hunted the blue whale (*Balaenoptera musculus*), Earth's largest animal, nearly to extinction. These whales reproduce very slowly: they live up to 10 years before becoming reproductively mature, produce only one offspring at a time, and have long intervals between births. Not surprisingly, the population has failed to recover.

Whether we want to manage the sizes of populations of desirable species for sustainable harvesting or of undesirable species for control purposes, the same principles apply. If the dynamics of a pest population are influenced primarily by density-dependent factors, then killing part of that population will only reduce it to a density at which it reproduces at a higher rate. A more effective approach to reducing such a population is to remove its resources, thereby lowering the carrying capacity of its environment. For example, we can rid our cities of rats more easily by making garbage unavailable (reducing the carrying capacity of the rats' environment) than by poisoning rats (which only increases their reproductive rate).

Biological control is the use of the natural enemies (predators, parasites, or pathogens) to reduce the population density of an economically damaging species (see the opening of Chapter 30). In many cases, the target species is a pest only because it has been introduced to a new area. Natural enemies used for

biological control are often obtained from the native region of the pest species. Biological control became popular in the nineteenth century after an outbreak of cottony-cushion scale, an Australian insect that attacks citrus, appeared in the citrus groves in California. A predaceous ladybeetle and a parasitic fly were then introduced from Australia and, within a year of their release, brought the scales under control.

On occasion, introduced predators and parasites not only fail to have any effect on the pest they were imported to control but, freed of their own enemies, they themselves become pests. This fact underlies the horror story of the cane toad (*Bufo marinus*) in Australia. These Central American toads (Figure 55.14) were introduced to control cane beetles attacking Australian sugarcane fields. But Australian cane beetles stay high on the upper stalks of the plants; the toads could not reach that high, and thus had no effect on the beetle population. Unfortunately, they had massive effects on other species.

All stages of the *B. marinus* life cycle are poisonous, and Australian reptiles (including snakes and lizards) and mammals that eat them usually die. With no enemies to limit their population growth, cane toads grow fast and outcompete native amphibian species for resources. The toads have spread from northern Australia down the east coast, where they threaten native frog species. The Australian government is forced to spend millions of dollars in attempting to reduce their numbers.

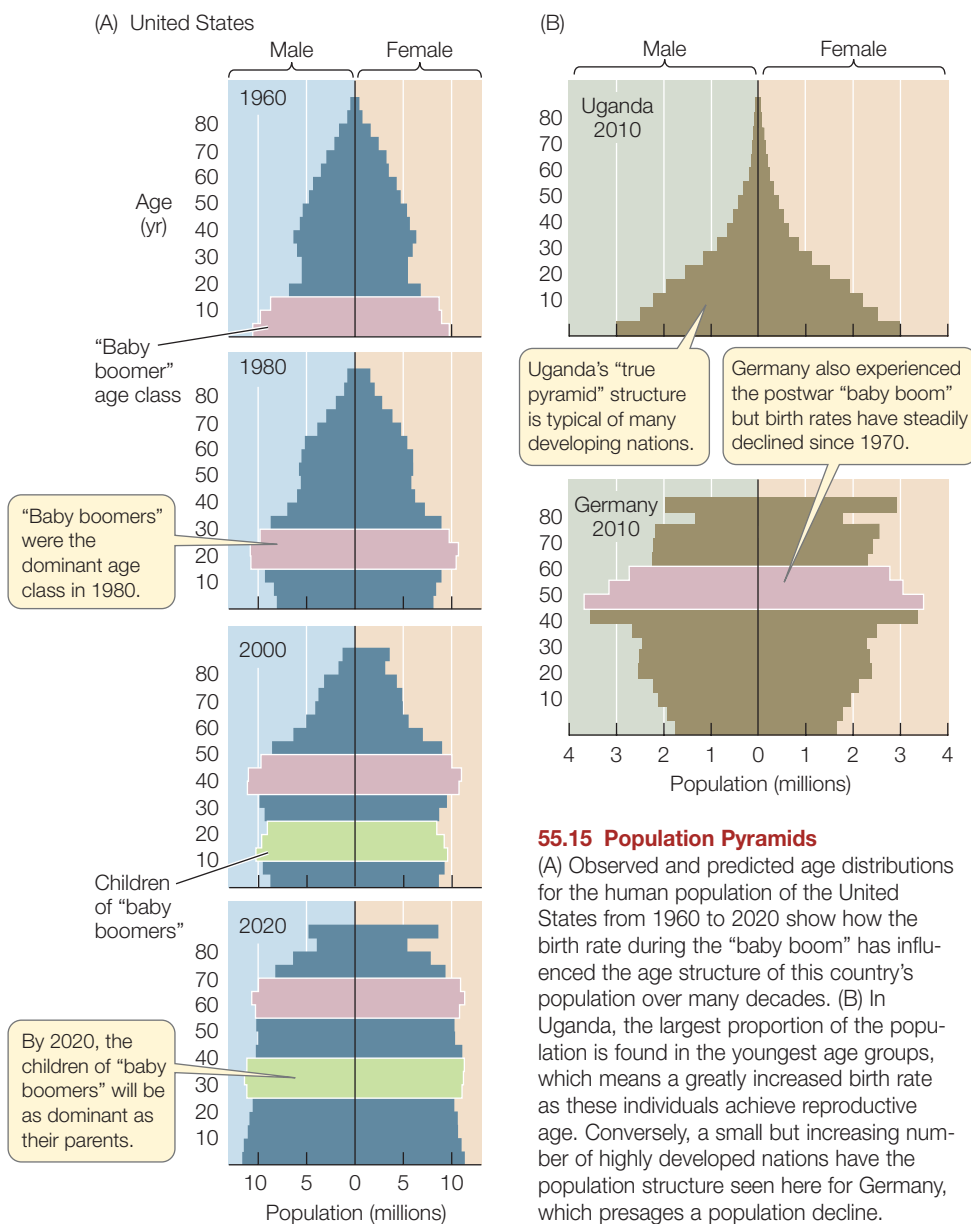

Human population increase has been exponential

In the nineteenth century, the historian Thomas Carlyle declared economics to be “the dismal science.” He was referring in part to a famous essay written a century earlier by Thomas Malthus, in which Malthus pointed out that the human population was growing exponentially but its food supply was not, and at some point famine and death would be the ultimate fate of the

Bufo marinus

55.14 Biological Control Gone Awry The Central American cane toad not only failed to control destructive beetles in Australia's sugarcane fields, but increased dramatically in abundance and now threatens many native Australian species.

55.15 Population Pyramids

(A) Observed and predicted age distributions for the human population of the United States from 1960 to 2020 show how the birth rate during the "baby boom" has influenced the age structure of this country's population over many decades. (B) In Uganda, the largest proportion of the population is found in the youngest age groups, which means a greatly increased birth rate as these individuals achieve reproductive age. Conversely, a small but increasing number of highly developed nations have the population structure seen here for Germany, which presages a population decline.

the current worldwide rate of increase to be about 1.1 percent per year—but with a base of 7 billion, even a minimal growth rate means millions more individuals.

Human populations are not growing at the same pace across the world, however. As we saw in Figure 55.2, in populations of long-lived species such as elephants and humans, the timing of births and deaths affects the age distribution for many years. Between 1946 and 1964, the United States experienced a "baby boom." During those years, almost 75 million babies were born, and the average number of children per family grew from 2.5 to 3.8. Birth rates declined during the 1960s, but in the 1970s and 1980s, the baby boomers became parents, generating another demographic bulge—a "baby boom echo" (Figure 55.15A). Today, the echo babies are entering college in record numbers (and reading about themselves in introductory biology textbooks), and are on the threshold of becoming the dominant age class.

The age structure of the U.S. population is typical of many industrialized nations, but a few highly developed nations (particularly in Europe) are experiencing population declines. In the developing world, however, many countries are experiencing exponential growth rates and have populations highly skewed toward younger age classes, portending high rates of population growth in the future (Figure 55.15B).

55.5 RECAP

Efforts to manage populations are more likely to be successful if they are based on an understanding of life histories and population dynamics.

- Describe an effective strategy for reducing a pest population and explain why it is effective. **See p. 1181**
- How have humans changed the carrying capacity of Earth for our own population? **See p. 1182**

human race. Neither Malthus nor Carlyle could have anticipated the technological innovations that greatly enhanced the capacity of humans to produce food. Today, however, the size of the human population is once again a serious concern as we confront the effects of our contributions to pollution, widespread habitat destruction, and the extinction of other species.

For thousands of years, Earth's carrying capacity for humans was low due to the relative inefficiency with which humans could obtain food and water. The development of social systems and communication, the domestication of plants and animals, ever-increasing crop and livestock yields through ongoing technological advances, and increasing proficiency at managing diseases have all contributed to unprecedented growth of the human population. It took more than 10,000 years for the population to reach 1 billion, which happened at some point in the late nineteenth century. Today, a mere 125 years later, the planet is home to approximately 7 billion human beings. Population growth has slowed somewhat from its post-World War II highs—the World Resources Institute estimates

Earth's carrying capacity for humans is set in part by the biosphere's ability to absorb the by-products—especially carbon dioxide—of our enormous consumption of fossil fuel energy; by water availability; and by whether we are willing to tolerate the extinction of millions of other species in order to accommodate our prodigious use of Earth's resources. We enumerate some of the effects of human resource use on other species in Chapters 58 and 59, but first Chapters 56 and 57 discuss the nature of species interactions and the formation of ecological communities.

CHAPTER SUMMARY

55.1 How Do Ecologists Study Populations?

- A **population** consists of the individuals of a species that interact with one another within a particular area at a particular time.
- The **density** of a population is the number of individuals per unit of area or volume.
- The **age structure** and **dispersion** pattern of a population influence its dynamics. [Review Figures 55.2 and 55.3](#)
- **Life tables** provide summaries of demographic events in a population. A cohort life table tracks a **cohort** of individuals born at the same time and records the **survivorship** or **fecundity** of those individuals over time. [Review Tables 55.1 and 55.2](#)
- Life table data can be used to construct a **survivorship curve**. [Review Figure 55.4](#)

55.2 How Do Environmental Conditions Affect Life Histories?

- The **life history strategy** of an organism describes how it partitions its time and energy among growth, maintenance, and reproduction.
- A population's **intrinsic rate of increase** (r) is the difference between the per capita birth rate (b) and the per capita death rate (d).
- Life history traits within a species may vary with habitat and interactions with other species can influence the evolution of life history traits.

55.3 What Factors Limit Population Densities?

- Populations can exhibit **exponential growth** for short periods, but eventually their resources become depleted, causing birth rates to drop and death rates to rise. [Review Figure 55.6, ANIMATED TUTORIAL 55.1](#)
- **Logistic growth** is the pattern seen when the growth of a population slows as its density approaches the environmental **carrying capacity** (K). [Review Figure 55.7, ANIMATED TUTORIAL 55.2 and WEB ACTIVITY 55.1](#)

- Species that are r -strategists have life histories that allow for high intrinsic rates of increase. K -strategists persist at or near the carrying capacity (K) of their environment. Many species' life history strategies fall along a continuum between these two extremes. [Review Figure 55.8](#)
- Population densities are determined by both **density-dependent** and **density-independent** factors. Several factors—including resource abundance, body size, social organization, and the length of time a species has occupied an area—influence population densities.

55.4 How Does Habitat Variation Affect Population Dynamics?

- No species is found everywhere within its mapped range. Members of most species live in distinct **habitat patches**.
- A **metapopulation** consists of separate subpopulations among which some individuals move on a regular basis. [Review Figure 55.10](#)
- Extinction of a subpopulation may be prevented by immigration of individuals from another subpopulation, a process known as the **rescue effect**. **Corridors** between patches may facilitate such movement. [Review Figure 55.11, ANIMATED TUTORIAL 55.3](#)

55.5 How Can Populations Be Managed Scientifically?

- To manage populations, it is important to understand their life histories and population dynamics. To maximize the number of individuals that can be harvested from a population, the population should be kept well below carrying capacity.
- Reducing the carrying capacity of the environment for a pest species is a more effective way to reduce its population than killing its members.
- Earth's carrying capacity for humans depends on our use of resources and the effects of our activities on the environment. Human populations grow at different rates in different parts of the world. [Review Figure 55.15](#)

SELF-QUIZ

- The way in which the individuals in a population are spread over the environment describes that population's

7. Density-dependent factors are population-regulating factors that
 - a. affect the same proportion of individuals regardless of population size.
 - b. are usually weather-related.
 - c. affect only sessile organisms.
 - d. influence only fecundity.
 - e. have effects that vary depending on population size.
8. A metapopulation is
 - a. an unusually large population.
 - b. a population that is spread out over a very large area.
 - c. a group of subpopulations among which some individuals move occasionally.
 - d. a group of subpopulations that are isolated from one another.
 - e. a group of subpopulations among which individuals move on a regular basis.
9. The best way to reduce the population of an undesirable species in the long term is to
 - a. reduce the carrying capacity of the environment for the species.
 - b. selectively kill reproducing adults.
 - c. selectively kill prereproductive individuals.
 - d. attempt to kill individuals of all ages.
 - e. sterilize individuals.
10. Populations that are most readily overharvested are characterized by having
 - a. very long-lived adults.
 - b. short prereproductive periods and many offspring.
 - c. short prereproductive periods and few offspring.
 - d. long prereproductive periods and few offspring.
 - e. long prereproductive periods and many offspring.

FOR DISCUSSION

1. Most organisms that humans manage for higher densities are long-lived and have low reproductive rates, whereas most organisms that humans want to reduce are short-lived but have high reproductive rates. What is the significance of these differences for management strategies and the effectiveness of management practices?
2. In the mid-nineteenth century, the human population of Ireland was largely dependent on a single food crop, the potato. When a disease caused the potato crop to fail, the Irish population declined drastically for three reasons: (1) a large percentage of the population emigrated to the United States and other countries; (2) the average age of a woman at marriage increased from about 20 to about 30 years; and (3) many families starved to death rather than accept food from Britain. None of these social changes was planned at the national level, yet all contributed to adjusting the population size to the new carrying capacity. Discuss the ecological principles involved, using examples from other species. What would you have done had you been in charge of the national population policy for Ireland at that time?
3. One method of controlling introduced pest species is to introduce a natural enemy (a predator, parasite, or pathogen) from the pest's native habitat to reduce its population density. However, some species introduced to control a pest have become pests themselves. Some scientists argue that biological controls should not be used under any circumstances for pest management. Others argue that, provided they are properly studied and thoroughly vetted, we should continue to use biological control organisms as part of our set of tools for managing pests. Which view do you support, and why?

ADDITIONAL INVESTIGATION

The arthropods whose metapopulation dynamics were studied in the experiment described in Figure 55.11 were all tiny animals with limited dispersal abilities. How could experiments be designed to test the influence of corridors on the metapopulation dynamics of species such as birds, lizards, and mammals, which readily disperse across large areas? Would you expect the results of such experiments to be similar to those using small arthropods on rocks? Why or why not?

WORKING WITH DATA (GO TO yourBioPortal.com)

Dead Sheep Tell a Tale Vertical life tables are constructed by sampling a population at a single point in time, across all age classes and life stages (thus their designation as “vertical”). One way to construct such a table is to record information from a *death assemblage*—the remains or fossils of the organisms in a given population. In this exercise, you will use data from a 1944 study of the skulls of more than 600 Dall sheep (*Ovis dalli dalli*) in Denali National Park, Alaska to create a vertical life table and survivorship curve for this population.

Habitat Fragmentation Figure 55.11 focuses on one of a series of experiments conducted by Andrew Gonzalez and Enrique Chaneon on population density and species diversity among moss-inhabiting mites. This exercise provides further data from these ingenious experiments and asks you to assess their implications for species diversity in fragmented environments.

Anty biotics

Familiar sights in Neotropical forest communities, “leaf-cutter” or “parasol” ants owe their name to their habit of clipping bits of leaf material from trees and carting them off to their nests. The leaves they collect, however, are not for their own consumption. Leaf-cutter ants are fungus farmers: they use the cut leaves as a substrate for growing the fungi on which they feed.

When a new queen ant is ready to leave the nest where she grew up, she packs her cheek pockets with a pellet containing pieces of the fungal mass that dominates her home. After mating, she lands, sheds her wings, and digs into the soil to form a tunnel with an enlarged end. There she ejects the fungal pellet and defecates in it. As the fungus begins to grow, the female lays eggs in it. With time, her eggs are engulfed by fungus, on which the hatching ant grubs feed. These first hatchlings develop into pint-

sized workers that leave the nest to collect leaf material to “feed” the growing fungus.

As the colony increases in size, more nest chambers are constructed, and the fungus garden expands; by its third year, the total number of chambers in a colony can exceed several hundred. Colony size is one factor accounting for the reputation of leaf-cutters as pests; it takes more than 2 kg of plant material per day to maintain the enormous fungal garden that nourishes the colony, so these ants can easily strip an area of vegetation.

The ants diligently care for the fungi. In addition to supplying leaves to the garden, they add fertilizer (in the form of their own feces) and regulate the humidity of the chambers. They are even able to distinguish and exclude leaves containing chemicals with fungus-killing properties.

The fungal gardens, however, are vulnerable to invasion by undesirable microbes, particu-

larly the virulent green mold *Escovopsis*. To guard against mold invasion, the ants carry around a supply of bacteria in special organs on their exoskeletons, called crypts. These bacteria manufacture powerful antibiotics that suppress the unwelcome mold, but do no harm to the cultivated fungus in the nest.

In the first written description of leaf-cutter ants, the

Feeding a Partner Central American leaf-cutter ants (*Atta cephalotes*) transport leaf fragments to their nest. The leaves will serve as food for the fungus they grow.

A Fungal Garden Cutaway view of a South American leaf-cutter ant nest chamber filled with fungus. Several winged ants (*Atta colombica*) can be seen in the crevices of the fungal mass.

Spanish priest Bartolome de la Casas decried their assiduous leaf gathering and massive nests, “white as snow,” as impediments to the cultivation of citrus and cassava in Hispaniola in 1559. The notion that these ants actually cultivate and eat the white fungus in their nests did not occur to anyone until the naturalist Thomas Belt introduced the idea in 1874. The existence and roles of the intrusive green mold and friendly bacteria were not documented until 1999, after another 125 years. It is not beyond the realm of possibility that even more interactions between species are involved in this system and remain to be revealed.

IN THIS CHAPTER we will examine how antagonistic interactions benefit one species at the expense of another, how mutualistic interactions benefit two or more interacting species, and how competition for the same resources affects the species involved. Throughout these discussions, we will see not only how these interactions influence the lives of these organisms, but how they shape species over the long range of evolution.

CHAPTER OUTLINE

- 56.1** What Types of Interactions Do Ecologists Study?
- 56.2** How Do Antagonistic Interactions Evolve?
- 56.3** How Do Mutualistic Interactions Evolve?
- 56.4** What Are the Outcomes of Competition?

56.1 What Types of Interactions Do Ecologists Study?

One of life’s certainties is that, at some point between birth and death, every individual organism will encounter and interact with individuals of other species. These interactions have consequences that can affect the individual’s fitness. Thus they can influence the densities of populations, the distributions of species, and, over the long term, lead to evolutionary change in one or both of the interacting species.

Interactions among species can be grouped into several categories

Although the actual number of interactions that take place among living things on Earth is essentially limitless, ecologists group interactions between species into a few basic categories. These categories reflect whether the outcome of the interactions is positive (+), negative (–), or neutral (0) for each of the species involved (**Figure 56.1**). The five broad categories of species interactions that we introduce in this chapter are *antagonistic interactions*, *mutualism*, *competition*, *commensalism*, and *amensalism*.

Antagonistic interactions are those in which one species benefits and the other is harmed. Antagonistic interactions include *predation*, in which an individual of one species kills and consumes multiple individuals of other species during its lifetime; *herbivory*, in which an individual of another species consumes part or, more rarely, all of a plant; and *parasitism*, in which one species consumes only certain tissues in one or a few individuals of another species without necessarily killing those individuals—known as *hosts*. Some parasites are *pathogens*, which cause symptoms of disease in their hosts.

Mutualism is a type of interaction between species that benefits both species. The interaction between leaf-cutter ants and fungi described at the opening of this chapter is an example of mutualism: the ants feed and cultivate the fungi, and the fungi, in turn, serve as food for the ants. Mutualisms exist between widely varied pairs of partners, including not only animals and fungi, but also fungi and plants, animals and plants, animals and animals, and microbes and all other kinds of organisms.

Competition between species refers to interactions in which two or more species use the same resource. The outcomes of these interactions depend on resource availability. Competition can occur along with almost any other kind of interaction: between predators that depend on the same prey species, between herbivores that depend on the same host plant, or between pathogenic microbes attacking the same host. The limiting resource need not be food; species may compete for water, for space, or even, in the case of plants, for sunlight.

(A)

Major types of species interactions			
TYPE OF INTERACTION	EFFECT ON SPECIES 1	EFFECT ON SPECIES 2	
Antagonistic interactions	Predation (predator–prey)	+	–
	Herbivory (plant–herbivore)	–	+
	Parasitism (parasite/pathogen–host)	+	–
	Mutualism	+	+
	Competition	–	–
	Commensalism (commensal–host)	+	0
	Amensalism	0	–

56.1 Types of Interactions (A) Interactions among species can be grouped into categories based on whether their influence on each of the interacting species is positive (+), negative (–), or neutral (0). These interactions can be broadly grouped as antagonistic or mutualistic. (B) Even a small scene can encompass many different species interactions.

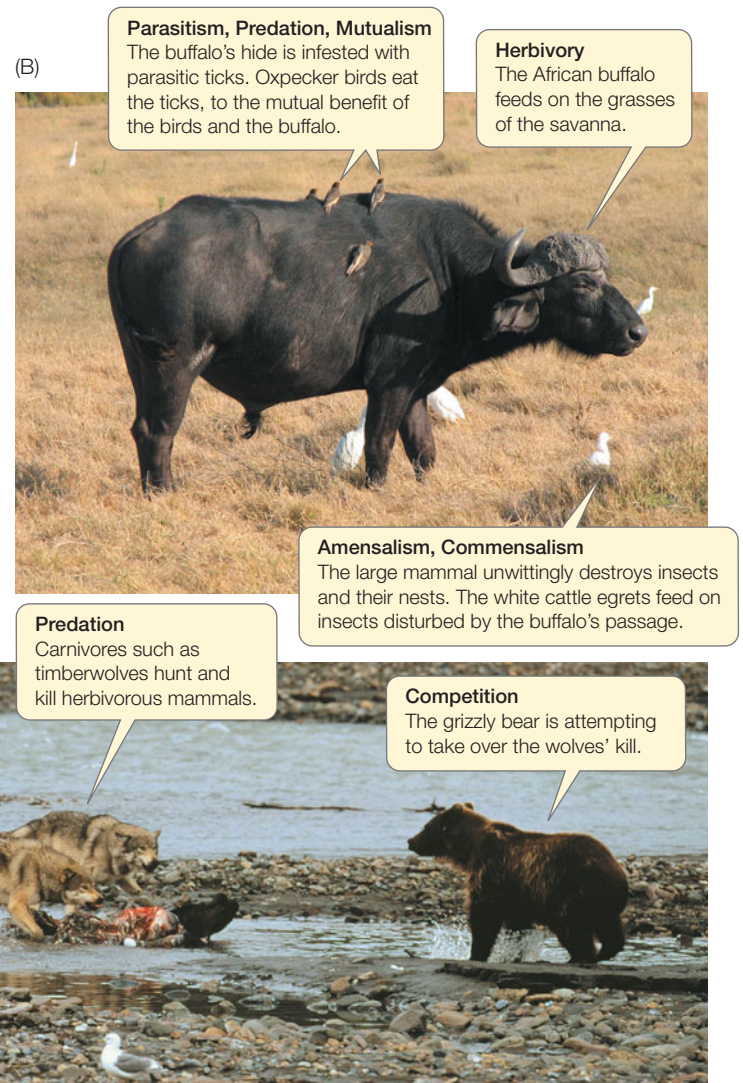

—yourBioPortal.com—

GO TO Web Activity 56.1 • Ecological Interactions

Predation, mutualism, and competition all affect the fitness of both participants, but there are two other types of interactions that affect only one participant. **Commensalism** is a type of interaction in which one participant benefits, but the other is apparently unaffected. Most examples of commensalism (from the Latin, “eating together”) involve one species feeding in, on, or around another species. For example, one species may associate with another species that, by virtue of its own feeding behavior, makes food more accessible. The brown-headed cowbird owes its name to its habit of following herds of grazing cattle, foraging on insects flushed from the vegetation by their hooves and teeth (in years past, it was called the buffalo bird because it followed the bison that were once abundant across the North American continent).

Another form of commensalism involves association for the purpose of transport, often to reach food resources that are rare and short-lived. Piles of mammal dung, for example, are a valuable resource for some detritivores, but they can be hard to find and never last long. Many kinds of detritivores that cannot fly—mites, nematodes, and even fungi—attach themselves to the bodies of dung beetles, which not only can fly but are also very good at locating fresh dung (as described in the opening story of Chapter 54). These hitchhikers have no effect on the dung beetle’s fitness, nor do cowbirds have any on the cattle that flush insects for them.

(B)

Amensalism is a type of interaction in which one participant is unaffected while the other is harmed. A herd of elephants moving through a forest crushes insects and plants with each step, but the elephants are unaffected by this carnage. Amensal interactions tend to be more random, and thus less predictable, than other types of interactions.

Although ecologists find it useful to group interactions between species into a few basic categories, the boundaries between categories are not always clear. For example, sea anemones in the Pacific Ocean sting and eat small fish, but a select few fish species (mostly in the genus *Amphiprion*) live inside sea anemones and are unaffected by their stings. These anemonefish move freely among the stinging tentacles to scavenge the cnidarians' leavings and even steal their prey (**Figure 56.2**).

Anemonefish must acclimate to the anemone's venom, and the anemone, in turn, must acclimate to the fish. The acclimation process appears to involve a change in the mucus coat of the fish; wiping off the mucus of an acclimated fish results in immediate stinging, whereas anemones will not attack fish with intact mucus. Although the benefit to the anemonefish is clear—it escapes its own predators by hiding behind the anemone's

Amphiprion ocellaris

56.2 Interactions between Species Are Not Always Clear-Cut

Ecologists long believed that the relationship between sea anemones and anemonefish was a commensalism: that the fish, by living among the anemone's stinging tentacles, gained protection from its predators. But could it also be considered a mutualism—if the fish's feces provide the anemone with beneficial nutrients—or competition—if the fish occasionally steals the anemone's prey?

nematocysts, and it has no need to forage widely for food—the anemones may benefit from the association as well. By defecating while in residence, the anemonefish may provide nitrogen-rich nutrients to the anemones.

The interaction types described in this section are in reality part of a continuum, and their outcomes depend on both ecological and evolutionary circumstances, including the presence and influence of other interacting parties.

Some types of interactions result in coevolution

All types of interactions have the potential to influence the population densities of the interacting species. By contributing to the differential survival or reproduction of genotypes, they can also alter gene frequencies within the populations over time. Thus these interactions have ecological consequences, as when they affect the distribution and abundance of individuals within a species, as well as evolutionary consequences, as when they lead to adaptations. In some cases, an adaptation in one species may lead to the evolution of an adaptation in a species it interacts with, a process known as **reciprocal adaptation** or **coevolution**.

Darwin saw the fitness of an organism as a measure of whether it gains or loses from interactions with other species. He noted, too, that evolutionary change occurs not only in response to physical conditions, as we saw in Section 54.2, but also in response to interactions among organisms. In his introduction to *The Origin of Species*, Darwin pointed out that woodpeckers have feet, tails, beaks, and tongues “admirably adapted to catch insects under the bark of trees” as a result of their long-standing interactions with their insect prey. Organisms can thus influence the evolution of the organisms with which they interact.

While abiotic factors also act as agents of selection, they differ in a fundamental way from biotic agents of selection in that they do not themselves undergo change as a result of the interaction. Snow and ice cannot increase their killing power as a result of encountering cold-resistant organisms, but predators can, over evolutionary time, become swifter, more powerful, or more efficient at capturing their prey. In response, prey species can, over evolutionary time, become swifter, tougher, less conspicuous, or more poisonous to decrease the likelihood of being consumed. The insect prey of Darwin's woodpeckers, for example, might evolve features that make them more difficult for the woodpeckers to find and capture.

A series of reciprocal adaptations can lead to what has been dubbed a coevolutionary **arms race**. The arms race analogy, first used in the context of interactions between herbivores and plants, can be applied to most antagonistic interactions. The evolution of traits that increase the fitness of a predator or parasite species exerts selection pressure on its prey or host species to counter the consumer's adaptation. The prey or host adaptation, in turn, exerts selection pressure on the consumer to improve its fitness, resulting in an escalating arms race. The types of interactions most likely to lead to coevolution, then, are those that occur predictably with high frequency over time and that have a strong effect on the interacting species; thus most amensal and commensal interactions are less likely to coevolve than are many plant–herbivore, predator–prey, and mutualistic interactions.

56.1 RECAP

Species interactions can be grouped into five categories based on whether they benefit or harm the species involved. Some species interactions can lead to reciprocal adaptations, or coevolution.

- Describe the five categories of interactions between species. **See pp. 1186–1187 and Figure 56.1**
- Explain the concept of a coevolutionary arms race. **See p. 1188**

Now let's take a closer look at antagonistic interactions. In Section 31.3 we looked at a number of feeding strategies from the consumer's point of view. In this section we will see how the interactions of consumers with their resource species influence both species.

56.2 How Do Antagonistic Interactions Evolve?

Every species serves as a food resource, in one way or another, for at least one other species. Consumers can increase their fitness by acquiring food, whereas resource species can increase their fitness by avoiding being consumed. Thus the interests of consumer and resource species set up an antagonistic relationship that can lead to a coevolutionary arms race. These consumptive relationships need not, however, be fatal; organisms make meals of one another in many different ways.

(A) *Panthera tigris*(B) *Cicindela campestris*(C) *Platythelphusa* sp.

56.3 Predators Use Many Weapons (A) Tigers embody most people's image of a predator—a large animal that uses speed, strength, teeth, and claws to capture prey. (B) The 1.3-cm green tiger beetle is also formidable to its prey, including caterpillars. Its huge jaws account for most of its body length, and it is among the swiftest runners among the insects. (C) *Platythelphusa* crabs of Lake Tanganyika have tremendously strong “toothed” claws with which they crush their snail prey. In an evolutionary arms race, thick shells have evolved in the snails.

Predator–prey interactions result in a range of adaptations

Predator–prey interactions are probably the most familiar, and the most dramatic, type of antagonistic interaction. Predators invariably kill the individuals they consume—referred to as their *prey*—and over its lifetime, a predator kills and consumes many prey individuals. Predators tend to be less specialized than other types of consumers.

The fitness of predators depends on balancing the cost of pursuing, subduing, and handling prey against the energetic return from consuming it. Thus many predators are larger than their prey, and many of them use strength or swiftness to capture prey. This is true of predators of all sizes: tigers pursuing deer and tiger beetles pursuing smaller insects are both swift, powerful, and equipped with strong jaws (**Figure 56.3A,B**). The few predators that are smaller than their prey rely on other strategies that increase their efficiency. Spiders, for example, capture their prey in webs. The short-tailed shrew, among the smallest mammalian predators, produces venomous saliva that paralyzes not only earthworms and snails, but also prey much larger than itself, including mice and small birds.

Prey species have many different kinds of defenses against predators. Many animal species can escape from predators simply by running away. Others have morphological defenses. Tough skin, shells, spines, or hair can foil even a determined predator. A coevolutionary arms race between predators and prey can explain why the lumpy-clawed crabs with the great-

est claw strength are found in the vicinity of snail prey with the thickest, most crush-resistant shells (**Figure 56.3C**).

CHEMICAL DEFENSES Many animals use chemical defenses to escape or repel their predators. Chemical defenses are generally the province of animal prey that are small, weak, sessile, or otherwise unprotected. Among the mollusks, for example, the weaker a species' shell, the more likely it is to use chemical defenses (see **Figure 56.4B**). Some vertebrates also rely on chemicals to repel their predators.

Many insects produce sprays, oozes, or froths when attacked. Bombardier beetles, for example, possess a pair of glands near the anal opening. Each gland has two compartments lined with a protective cuticle. The inner compartment contains a mix of relatively nontoxic chemicals, along with hydrogen peroxide. The outer compartment contains enzymes. When the beetle is disturbed, it discharges the contents of the inner compartment into the outer compartment, which leads to an instant, energy-releasing chemical reaction. Oxygen is one of the end products generated by this reaction, and the resulting pressure discharges the mixture with an audible “pop.” Due to the energy of the reaction, the temperature of the spray is approximately 100°C. The reaction of predators—including humans—to this hot, explosive secretion is predictable, and bombardier beetles have very few enemies.

But predators may evolve to overcome their prey's chemical defenses, as we saw in the case of the rough-skinned newt and the garter snakes that have become insensitive to its protective toxin (see **Figure 21.22**). Some predators are not only undeterred by their prey's defensive chemicals, but ingest them and sequester them in their bodies as defenses against their own predators. Some sea slug species, for example, acquire their defensive chemicals from the toxic sponges they can eat with impunity. Many prey species that defend themselves with toxicity advertise that fact, a phenomenon called *aposematism*.

APOSEMATISM Some prey species exploit the fact that predators can learn to avoid certain warning signals. Many toxic prey sport bright colors or striking patterns. Such warning coloration, or **aposematism**, increases the probability that a predator will

*Danaus plexippus* larva*Tetraopes tetraophthalmus**Aphis nerii*

56.4 Some Prey Come with Warning

Labels (A) Milkweed plants are toxic, and many of the insects that feed on them—including monarch butterfly larvae, milkweed beetles, and aphids—incorporate the plant's toxic chemicals into their systems. (B) Nudibranchs (sea slugs) are mollusks without protective shells, however, they may possess stinging nematocysts (acquired from their hydrozoan prey), and their bright coloration warns predators away. (C) Dart poison frogs of Central and South American sequester highly toxic chemicals in their brightly colored skin.

(B) *Chromodoris* sp.(C) *Dendrobates reticulatus*

learn to recognize and avoid a toxic species (**Figure 56.4**). Certain visually hunting predators, particularly among the vertebrates, can learn quickly to associate certain color patterns with an unpleasant dining experience. Thus aposematic species are characteristically tough enough to survive a brief encounter with a predator. Any encounter that results in the death of the aposematic individual is unlikely to result in selection for that aposematic pattern. Aposematic butterflies in the field often sport beak marks, an indication of having survived a taste by an uneducated avian predator. And, as it turns out, even non-toxic species can benefit by mimicking warning coloration.

MIMICRY SYSTEMS We have seen that some prey species avoid consumption by mimicking inedible objects. Others do so by mimicking aposematic species. This strategy has led to the evolution of mimicry systems of two types. In **Batesian mimicry**, a nontoxic species (the *mimic*) resembles a toxic species (the *model*) and benefits from the avoidance behavior learned by the predator in response to the toxic model species. For example, venomous bees and wasps sport distinctive yellow and black stripes that are models for harmless hover flies (**Figure 56.5A**). Mimicry may extend beyond physical appearance; many mimics also simulate distinctive behaviors of their models. Some hover flies, for example, vibrate their wings to buzz in beelike fashion.

In **Müllerian mimicry**, a number of aposematic species converge on a common color pattern; all benefit from providing a stronger recognition signal to predators. Many of the Neotropical zebra butterflies, which feed on toxic passionflower plants

and incorporate their toxins into their bodies, are Müllerian mimics (**Figure 56.5B**).

AVOIDING DETECTION Many prey species escape predators by hiding. One form of hiding is camouflage, or background matching, also called **crypsis** (**Figure 56.6A**). Some animals can even change their coloration to match the substrate they find themselves on. The camouflage of some species not only hides them but allows them to resemble objects their predators consider inedible, a strategy called **homotypy** (**Figure 56.6B**). The dead-leaf butterfly looks very much like a dead leaf, even down to the likeness of a spot of fungal decay, and swallowtail caterpillars look like bird droppings.

Because the vision of many types of predators is adapted to spot moving prey, many prey species simply stop moving if they are being pursued. “Playing possum,” a term that is sometimes applied to this strategy, refers to the ability of the opossum (*Didelphus virginianus*) to “play dead.”

Herbivory is a widespread interaction

The most ubiquitous interaction on Earth is that between plants and the herbivores that eat them. Herbivores have a relatively easy time acquiring food: plants are sessile and cannot bite, scratch, or run away. A conservative estimate puts the number of herbivore species (the vast majority of which are insects) at

(A) Batesian mimics

*Episyrphus balteatus*

This harmless hoverfly...

...mimics a stinging wasp.

*Vespula vulgaris***56.5 What You See Is What You Get—Sometimes**

(A) Batesian mimics are harmless species that gain protection from mimicking dangerous ones. (B) The shared aposematic coloration of Müllerian mimics is an honest advertisement of their toxicity. All the zebra butterflies (genus *Heliconius*) of South America feed on toxic passionflower plants and incorporate the toxins into their bodies. *Heliconius* species living in a particular area have similar warning colors.

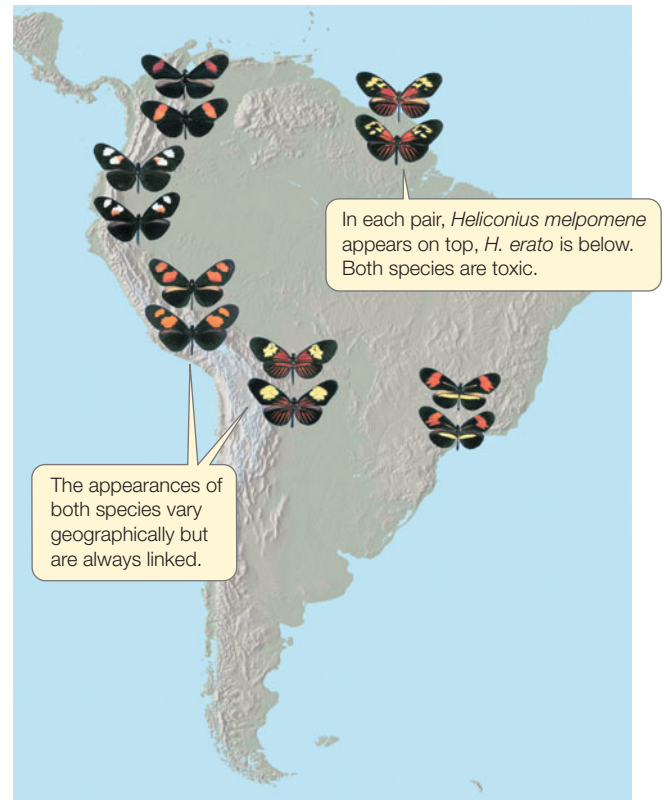

400,000 and the number of plant species they consume at over 300,000. Every major class of vertebrates includes at least a few herbivores. In marine systems, organisms that feed on plants and algae include mollusks, crustaceans, echinoderms, and annelids.

In terms of numbers of individuals as well as numbers of species, most of the world's herbivores are insects. Over 90 percent of these insects are *oligophagous*: specialists that dine on just one or a few, often taxonomically related, plant species. *Polyphagous* species, in contrast, feed on as many as dozens of unrelated plant species. Vertebrate herbivores are generally polyphagous; a cow grazing in a pasture, for example, can consume many different plant species in a single afternoon. There are exceptions to this pattern, however; Australian koalas famously feed exclusively on the foliage of eucalyptus trees, and the diet of giant pandas is made up almost entirely of bamboo.

Herbivores, particularly insects, generally consume only parts of their food plants, and usually do not kill them. In most natural ecosystems, insects rarely remove more than 20 percent of plant biomass. For that reason, questions occasionally arise as to the ability of insects to act as selective agents on plant traits. Mortality is not, however, the only form of selection that leads to evolutionary change; herbivores can reduce plant fitness if the plants they attack produce fewer offspring.

PLANT DEFENSES AGAINST HERBIVORES The defenses of plants against their diverse consumers are necessarily highly diverse. For most plant species, chemistry is the principal defense mechanism. As we saw at the opening of this chapter, the leaves of

(B) Müllerian mimics

some trees contain chemicals that prevent them from being consumed by fungi—and thus, incidentally, from being harvested by leaf-cutter ants. The amazing variety of secondary metabolites produced by plants to defend themselves against herbivores is the topic of Section 39.2. Many plants, however, have additional defenses.

(A) *Hyla versicolor*(B) *Mimetica* sp.

56.6 Avoiding Consumption by Avoiding Detection (A) The gray tree frog can change its coloration to blend in with its substrate, an example of crypsis. (B) Homotypy—resemblance to an inedible object—can be an effective defense against visually hunting predators. Birds searching for insect prey are likely to pass by a katydid that looks like a leaf.

Some plants protect themselves by being physically difficult to ingest. Thorns and spines are effective deterrents to browsing vertebrate herbivores. Smaller herbivores, including many insects, can be deterred by small hooked hairs on leaf surfaces. The soft bodies of leafhoppers can be pierced by these hairs, which fix the insect in place until it eventually dies from starvation or loss of blood. The cuticle may also act as a physical barrier. Most grasses contain silica, which wears down sharp edges of herbivore teeth. Insects that feed only on grasses tend to have chisel-like mandibles to slice through the leaf tissue; moreover, their heads are larger to accommodate the larger jaw muscles needed to process their food.

RECIPROCAL ADAPTATIONS IN HERBIVORES AND PLANTS The concept of reciprocal adaptation was first described in the context of interactions between herbivores and plants. In 1959, the entomologist Gottfried Fraenkel reached the conclusion after many years of study that all green plants are essentially nutritionally equivalent for insects. Why, then, are so many insects such picky eaters? Fraenkel proposed the novel hypothesis that ecological factors underlie the diversity of secondary metabolites that deter insect herbivores. A few years later, entomologist Paul Ehrlich and botanist Peter Raven proposed the following evolutionary scenario to account for patterns of host plant use among herbivorous insects (specifically, in their case, butterfly families):

- Certain plants, by mutation or recombination, evolve a novel secondary metabolite.
- If the chemical reduces the plant's appeal to herbivores, then plant genotypes producing the chemical are favored.
- Freed from mortality associated with herbivory, plants possessing the novel chemical undergo an adaptive radiation.
- Certain herbivores, by mutation or recombination, evolve resistance to the chemical, and these resistant herbivores undergo their own adaptive radiation.
- With sufficient selection pressure, a resistant herbivore can evolve to use the chemical as a defense against its own predators.

This stepwise coevolutionary process explains not only the biochemical diversity of flowering plants, but also the tremendous diversity of herbivorous insects. The ecological scenario outlined by Ehrlich and Raven is an example of the type of coevolutionary arms race described earlier in the chapter.

A tremendous diversity of adaptations to plant defenses have evolved in herbivores. Many herbivores circumvent plant defenses by behavioral means. For example, the secondary metabolites produced by a plant called Saint-John's-wort (*Hypericum perforatum*) require exposure to sunlight for optimal toxicity, so insects that feed on this plant roll its leaves into a light-impermeable cylinder and feed in comfort in the dark. The laticifer-cutting beetles described in Section 39.2 have a different method of detoxifying their food plant. Many large polyphagous herbivores, such as deer, horses and the like, graze on a wide variety of plant species, minimizing their exposure to any particular defensive chemical. Long-lived and with rel-

atively good memories, they can learn to avoid plants with an unpleasant taste.

Unlike large mammalian herbivores, caterpillars and many other insect herbivores may spend their entire lives feeding on a single individual plant. Such oligophagous diets are associated with highly specialized detoxification systems. The diamondback moth caterpillar eats plants in the cabbage family that are rich in toxic mustard oil glycosides. In its gut is an enzyme that breaks down the glycosides into harmless by-products, allowing it to eat these plants with impunity.

Some herbivores take resistance a step further by storing, or sequestering, plant toxins in specialized organs or tissues that are insensitive to those toxins. In this way, they can accumulate large quantities of toxins in their bodies with no ill effects. This strategy also makes the expropriated chemicals available for defense against the herbivores' own enemies. Caterpillars of the monarch butterfly, for example, are insensitive to the neurotoxic glycosides in their milkweed host plants, but most of their enemies, including insect-eating birds, cannot tolerate these compounds.

Yet the plants continue their side of the coevolutionary arms race. As we have seen, the principal consumers of passionflower plants are zebra butterflies. These oligophagous butterflies lay eggs only on passionflower plants, and their larvae sequester host plant toxins in their bodies as they feed on the leaves. Some passionflower species, however, have modified leaf structures that resemble the eggs of butterflies. Female butterflies will not lay eggs on plants already containing eggs, so the egg mimics reduce the plant's probability of being consumed (**Figure 56.7**).

Microparasite–host interactions may be pathogenic

Microparasites, such as viruses, bacteria, and protists, are many orders of magnitude smaller than their hosts and generally live and reproduce inside their hosts. Multiple generations of mi-

56.7 A Plant Uses Mimicry to Avoid Herbivory Passionflower leaves are modified to resemble the eggs of their principal herbivores, zebra butterflies (*Heliconius* spp.), which will not lay eggs on a plant already containing eggs. The egg mimics deter the female from laying eggs, thus protecting the plant from being eaten by hatching caterpillars.

croparasites may reside within a single host individual, and a host may harbor thousands or millions of them. Many microparasites, in the process of acquiring nutrients at the expense of their host, cause symptoms of disease—that is, they are *pathogens*. Section 39.1 describes the array of secondary metabolites that plants produce to defend themselves against pathogens, and Chapter 42 describes the defenses of animals.

Infection by pathogens may in some cases result in the death of the host, but death is by no means an inevitable outcome of these interactions. If a pathogen strain is to persist in a host population, the pathogens must continually infect new host individuals. A less deadly strain that kills a smaller proportion of host individuals may succeed in infecting a larger number of new hosts. Thus pathogen and host may reach a state of coexistence as increased host *resistance* (ability to withstand the effects of a pathogen) and decreased pathogen *virulence* (ability to cause disease) evolve. Yet new, virulent strains may also arise, reminding us that the arms race goes on.

Hosts of pathogens fall into three classes: *susceptible* (capable of being infected), *infected*, or *recovered* (and thus, in many cases, *immune*; see Chapter 42). A pathogen can readily invade a host population dominated by susceptible individuals, but as the infection spreads, fewer susceptible individuals remain to be infected. Eventually a point is reached at which most infected individuals no longer transmit the infection to susceptible individuals. Thus rates of infection typically rise, then fall, and do not rise again until a sufficiently large population of susceptible host individuals has reappeared.

Most ectoparasites have adaptations for holding onto their hosts

While microparasites generally live and reproduce inside their hosts, larger parasites, called *macroparasites*, are associated with their hosts in a slightly less intimate way. Although macroparasites rarely cause the same kinds of disease symptoms that pathogenic microparasites cause, they may nevertheless affect host survival and reproduction and can thereby act as selective agents on their hosts.

Some ectoparasites (external parasites)—leeches, mosquitoes, and the like—are only casually associated with their hosts, interacting with them just long enough to eat their fill and then moving on. Others spend their entire lives in or on their hosts. These ectoparasites have a number of attributes designed to keep them attached to their hosts. Crab lice, ectoparasites that are generally found in the pubic region of their human hosts, have claws on the tips of their legs that clamp around pubic hairs with great precision (Figure 56.8). Pulling off a crab louse will often leave the leg behind, still firmly attached to the hair. Ectoparasites have other adaptations designed to reduce the ability of irritated hosts to remove them, such as flattened bodies and a thick, tough cuticle. Many ectoparasites also have adaptations to a sedentary existence, such as loss of sensory organs and wings. Most ectoparasitic insects are highly specialized, sometimes feeding on only a single host species.

Most hosts actively work to rid themselves of their ectoparasites. The Japanese macaque, for example, is prone to infesta-

Phthirus pubis

56.8 Ectoparasites Can Make a Host Crabby Ectoparasites such as the human pubic (or “crab”) lice in this scanning electron micrograph tend to be tiny, wingless, flattened, and equipped with strong claws for gripping their host.

tion by two species of lice, which tend to lay their eggs on the outer surfaces of the host’s back, arms, and legs. An individual macaque may harbor more than 500 louse eggs, and would find it difficult to reach and eliminate all of them. To keep louse populations in check, macaques must form and maintain social bonds in order to ensure the consistent presence of grooming partners. Grooming behavior—an important component of the social interactions of many primates—may have evolved in response to ectoparasites. Some biologists believe that human hairlessness and bipedal posture (which freed the hands for manipulating small objects), as well as the opposable thumb, were evolutionary responses to ectoparasites.

56.2 RECAP

Predator–prey, herbivore–plant, and parasite–host interactions are all antagonistic. Consumers have adaptations for finding and utilizing their resource species with greater efficiency. The resource species in turn have adaptations that reduce their probability of being discovered, captured, and eaten.

- What are some of the adaptations that help prey species to avoid consumption by predators?
See pp. 1189–1190
- How are aposematism and mimicry related?
See pp. 1189–1190 and Figures 56.4 and 56.5
- Explain the scenario for coevolution between insect herbivores and their host plants proposed by Ehrlich and Raven. **See p. 1192**

Like antagonistic interactions, mutually beneficial interactions between species can result in reciprocal adaptation. A mutually beneficial exchange of goods or services can ensure the predictability and frequency of such interactions over evolutionary time; thus many mutualistic interactions are tightly coevolved.

56.3 How Do Mutualistic Interactions Evolve?

There are few, if any, taxonomic limits on the formation of mutualisms; animals, for example, can form mutualistic associations with other animals, with plants, and with a wide range of microorganisms. Mutualistic interactions often arise in environments where resources are in short supply. Consequently, many mutualisms involve an exchange of food for housing or defense. In another type of mutualism, many sessile organisms, particularly flowering plants, rely on more mobile species for mating or dispersal.

Many mutualisms are *asymmetrical*—in other words, one party benefits more than the other. One or both partners may evolve adaptations that ensure that the exchange benefits both of them. Reciprocal adaptations are most likely to arise in mutualistic interactions if an increase in dependency on a partner provides an increase in the benefits realized from the interaction. If increased dependence provides no selective advantage, mutualists (particularly those in asymmetrical mutualisms) may evolve into parasites, give up their partners for an independent existence, or even go extinct.

Plants and pollinators exchange food for pollen transport

For about three-quarters of the planet’s 250,000 flowering plant species, reproduction requires the transport of pollen by an animal partner. A mutualistic pollination system requires several features:

- An *attractant* or reward that entices a pollinator to visit the plant
- *Behavior* that ensures that a pollinator visits more than one individual of a plant species
- *Anatomical features* that allow a pollinator to transport the plant’s pollen

Flowers entice pollinators in many ways. The most direct reward for pollinators is the pollen itself, which sometimes serves as food. Pollen was probably the original attractant in the evolutionary history of plant–pollinator interactions. Plant reproduction would not be served, however, if pollinators were to eat *all* of a plant’s pollen; thus plants have evolved various adaptations to ensure that they benefit from the exchange. For example, some plants have two types of anthers: feeding anthers to produce pollen for pollinators, and fertilization anthers to produce pollen for reproduction. These two types of anthers

56.9 Plants Sometimes Take Advantage of Their Pollinators This orchid (*Ophrys insectifera*) has flowers that look and smell like a female wasp. Male wasps (*Argogorytes mystaceus*) will pollinate the flower while trying to mate with it.

are shaped and positioned differently, so that as the pollinator dines on pollen from the feeding anthers, the fertilization anthers deposit pollen on a part of its body that will transfer it to the stigma of another flower of the same species.

Plants, like pollinators, may take advantage of their partners. Some species have evolved flowers that bear a striking resemblance to females of a particular wasp species (in some cases even producing the same chemical substance that the female wasp uses as a sexual attractant pheromone). Male wasps, in a futile effort to copulate with the flower, get pollen on their bodies, which they deliver to the next flower they visit in their effort to locate a genuine mate (**Figure 56.9**).

Compared with pollen, *nectar*, a sugar-rich solution produced by some angiosperms, is a relatively new evolutionary development. Of all floral rewards, nectar has the greatest appeal and is consumed by the widest range of animal pollinators, including not only insects but also birds (such as hummingbirds) and mammals (such as bats). While nectar serves to attract potential pollinators, it is prone to removal by *thieves*: flower visitors such as ants that can reach and consume the nectar without

TABLE 56.1				
Pollination Syndromes Resulting from Diffuse Coevolution				
PREFERRED POLLINATOR	FLOWER SHAPE	SUITE OF ANATOMICAL TRAITS ^a		
		FLOWER COLOR	REWARD	ODOR
Bees	Irregular	Many	Nectar, pollen	Sweet
Flesh flies	Irregular	Purplish	None	Carrion
Beetles	Bowl	White or pale	Pollen	Faint
Butterflies	Tubular platforms	Many	Nectar	Faint
Moths	Often pendant	White or pale	Nectar	Heavy
Hummingbirds	Tubular	Red	Nectar	Imperceptible
Bats	Cuplike	White or pale	Copious nectar	Musty

^a In many plant groups, diffuse coevolution has led to suites of traits (as opposed to a single trait) that are characteristic of the interactions between the plants and their preferred pollinators.

Taraxacum officinale

transporting pollen. Nectar thieves lower plant fitness by depleting nectar that would otherwise attract actual pollinators.

Plants not only need to attract pollinators, but must also ensure that those pollinators carry their pollen to other members of the same species. Repeat visits by a pollinator to different individuals of a particular plant species increase the likelihood that the pollen will end up on the appropriate stigma; thus some plants have adaptations to limit the diversity of their animal visitors. The depth and width of a flower can restrict the

56.10 See Like a Bee To normal human vision, a dandelion appears solid yellow. Ultraviolet photography reveals the patterns that attract bees to the region of the flower where pollen and nectar will be found. These patterns are invisible to humans and birds.

size and shape of the pollinator mouthparts that can gain access to their nectar. Timing of flowering can also restrict the number of potential pollinators and encourage pollinator fidelity. Floral characteristics influence the type of pollinator attracted initially. Ultraviolet wavelengths, for example, are highly attractive to bees (**Figure 56.10**) but invisible to most birds.

Most flowers can be successfully pollinated by a number of animal species. The evolution of broad suites of floral characteristics that attract certain groups of pollinators is an example of **diffuse coevolution**: the evolution of similar traits in suites of species experiencing similar selection pressures (**Table 56.1**). Scarlet gilia (*Ipomopsis aggregata*), a common wildflower in the Rocky Mountains, has successfully combined two strategies. Early in its growing season, it produces red flowers that attract hummingbirds; later in the season, the gilia shifts to producing white flowers because by then the most abundant pollinators are hawkmoths, which cannot see red but are attracted to white.

A few plant–pollinator relationships are much more exclusive; these lead to highly specific, rather than diffuse, coevolution. Yucca plants are pollinated only by a group of moths collectively known as yucca moths, whose larvae feed exclusively on yucca seeds. The stigma of the yucca flower is located fairly deep within the pistil, and fertilization will not occur unless pollen is physically placed there. The specialized mouthparts of female yucca moths have distinctive long tentacles, which the moths use to pack masses of pollen from one yucca flower into transportable balls that they then carry to another flower. The moth pushes the pollen ball deep into the recess in which the flower's stigma is tucked, then turns around and deposits her eggs inside the flower's ovule (**Figure 56.11**). When the eggs hatch, the caterpillars will consume some—but not all—of the

Yucca filamentosa

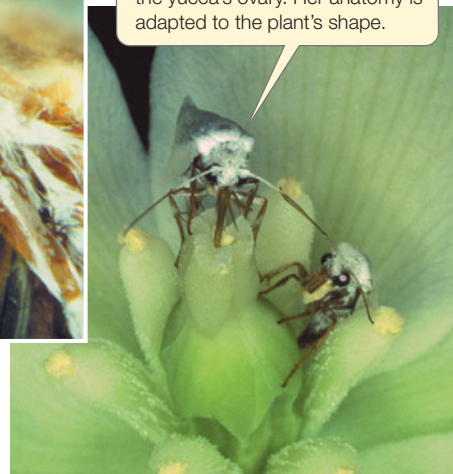

Tegeticula yuccasella

flower's developing seeds. Neither of these species can reproduce in the absence of the other.

Plants and frugivores exchange food for seed transport

Many animals that eat fruits provide a valuable service to the plants that produce them by dispersing seeds. Seed dispersal by animals offers plants the advantage of delivery to potential germination sites and comes with the bonus of organic fertilizer for the seeds. Interactions between plants and frugivores, however, are not always reciprocal; in many cases, one party benefits more than the other. Whereas the frugivore is paid “in advance” for transportation services, the seeds may never reach an appropriate destination for germination (your windshield, for example, will not do). From the plant's perspective, a partnership with frugivores requires a delicate balance between discouraging frugivores from eating fruits before the seeds are capable of germinating and attracting them when the seeds are ready. In addition, the plant must protect the seeds from destruction in the frugivore's digestive tract and defend them against inappropriate consumers that damage the seeds or fail to disperse them at all.

The chemical process of fruit ripening ensures that fruits are most attractive to frugivores when the seeds are mature and ready for dispersal. In many fruits, ripening is accompanied by a decrease in organic acids, which make many unripe fruits sour. Color changes, which result from loss of chlorophyll and the accumulation of other pigments (the conversion of peppers from green to red during ripening is an example), have enormous signal value to many frugivores. Green, unripe fruits are generally difficult for vertebrate frugivores to see against green foliage; red and bicolored red and black fruits contrast with foliage. Fruit softens as it ripens to allow for gentle processing by the frugi-

vore and rapid passage through its gut. Another conspicuous change in ripening fruits is an increase in sugar content—the “reward” most sought by frugivores. Seed coats, fruit pulp, and epidermis may all contain secondary chemicals designed to discourage inappropriate frugivores from consuming the fruit.

Because of the often asymmetrical nature of the mutualism between frugivores and plants, relatively few highly specialized frugivores exist. One apparently reciprocal interaction is between mistletoes—parasitic plants that grow on trees—and the mistletoe birds that serve as the plants' primary dispersal agents in Asia and Australia (**Figure 56.12**). These birds dine largely on the fleshy berries of mistletoe. The seeds, covered with a glue-like outer coat, experience little enzymatic or mechanical damage as they pass through the thin-walled guts of the birds that swallow them. When the seeds are voided with the bird's droppings, the sticky outer coat causes the seeds to adhere to the bird's vent feathers, prompting it to wipe its bottom across the tree branch on which it is perched. Once the seed is wiped on the branch, the gluey coat keeps it there—in an ideal location for a mistletoe seed to germinate.

Some mutualistic partners exchange food for care or transport

Some organisms, such as the leaf-cutter ants described at the opening of this chapter, get their food by “farming” fungus. Fungus farming has been documented in a wide variety of species, including bark beetles, termites, and even a snail. In most cases, the farmers provide housing, nutrition, and care for the fungal partner; the fungal species, in turn, provides food for the host. The fungus produces enzymes that can degrade plant proteins and cellulose, converting plant materials that the farmers cannot digest for themselves into an edible form.

Over the past 50 years, one fungus farmer, the southern pine bark beetle (*Dendroctonus frontalis*), has destroyed over a billion dollars' worth of pine forests in the southeastern United States (**Figure 56.13**). The beetle owes much of its efficiency to its mutualistic partners. Masses of adult beetles attack a pine tree at once, overwhelming the tree's ability to defend itself (the tree's defense is to release large quantities of resin under pressure to force out the beetles). The beetles then excavate a series of galleries through the vascular tissue underneath the bark, in which females lay their eggs. Female beetles also carry spores of their partner fungus into the galleries. The fungus grows on and breaks down the gallery walls; the beetles feed directly on the fungus and the partially digested wood. The beetles also transport a bacterium that produces an antibiotic to keep harmful bacteria from attaching to the fungus. This insect–fungus–bacteria partnership can overcome the trees' antiherbivore defenses, to their mutual benefit.

Some mutualistic partners exchange food or housing for defense

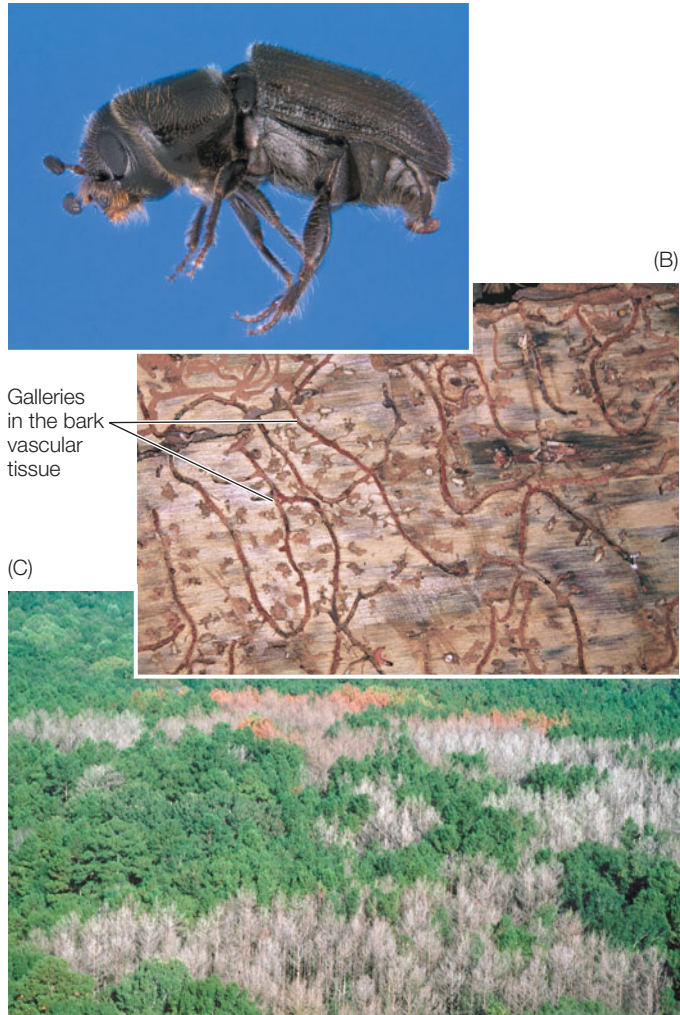

Some plants are not only resources, they are also mutualistic partners for insects. The best-known of these interactions is that between ants and acacia trees in Central America. In 1874, in Nicaragua, the naturalist Thomas Belt observed a peculiar inter-

Dicaeum hirundinaceum

56.12 A Frugivore Plants and Fertilizes A Seed at the Same Time

After a mistletoe bird eats the fruit of the parasitic mistletoe plant, the seeds inside the fruit pass through the bird's digestive tract intact. As the seeds are voided, their sticky outer coat makes them stick to the bird's feathers. As the bird wipes itself clean on a branch, the seed sticks to the branch, where it germinates.

**56.13 A Mutualistic Interaction Brings Death to Pine Trees** (A)

The southern pine bark beetle has a mutualistic relationship with a fungus, which it “farms” within the vascular tissue of pine trees. (B) The bark beetle excavates galleries inside the trees’ vascular tissue. Here they lay eggs and farm fungus; the fungus overcomes the trees’ defenses against the beetle and provides nutrition for the larvae. (C) Masses of bark beetles overwhelm pine forests, resulting in widespread death of pine trees.

action between bull’s horn acacia (*Acacia cornigera*) and *Pseudomyrmex* ants, known as acacia ants because they are found only in association with acacias. Bull’s horn acacias have enlarged hollow thorns in which the ants build nests. The trees produce nectar in specialized extrafloral structures and modified leaflet tips that are rich in oil and protein, on which the ants feed. These structures have no apparent purpose other than providing food for ants.

Belt suggested that the notoriously aggressive acacia ants defend the plants against their herbivores and competitors in exchange for food and shelter. But his idea was not tested until Daniel Janzen conducted an experiment in 1966. By removing ants from some acacias with insecticide, Janzen demonstrated that trees without ants suffered a reduction in growth and an increase in mortality (Figure 56.14). Ants also clipped weeds from around the base of the plants, presumably reducing competition for nutrients.

INVESTIGATING LIFE

56.14 Are Ants and Acacias Mutualists?

Bull’s horn acacia trees (*Acacia cornigera*) grow numerous structures that provide food and shelter for ants of the genus *Pseudomyrmex* (acacia ants). Daniel Janzen’s experiments demonstrated that the trees benefit greatly from their association with these ants, and that the energy expended in growing ant-attractive structures is repaid with increased growth and survival.

HYPOTHESIS *Acacia cornigera* trees deprived of their *Pseudomyrmex* ant populations will not thrive in comparison with trees populated by ant colonies.

The “bull’s horns” of these *Acacia* trees are enlarged, hollow thorns in which the ants build nests.

METHOD

1. Define a population of *A. cornigera* trees; designate some of them as untreated controls and the rest as experiment subjects.
2. Fumigate the experimental *A. cornigera* trees with insecticide to eliminate all *Pseudomyrmex* ants.
3. Apply Tanglefoot® (a sticky material) to the base of the fumigated experimental trees to prevent the ants from recolonizing them.
4. Record the survival and growth rates of the trees in both groups over a 10-month period.

RESULTS

After 10 months, control trees (with ants) had considerably higher survival rates and greater growth than did trees without ant populations.

**CONCLUSION**

Pseudomyrmex ants provide substantial survival benefits to *Acacia cornigera* trees.

56.3 RECAP

Mutualistic interactions involve an exchange of benefits. Most plants rely on mutualisms with mobile animals for fertilization and seed dispersal.

- Give examples of benefits that are exchanged in at least two mutualisms between plants and animals.
- What three features are required by a plant–pollinator mutualism? [See p. 1194](#)
- How are pollinator-plant interactions different from frugivore-fruit interactions? [See pp. 1194–1195](#)
- Describe some adaptations in plants that help to maintain the balance in their relationships with frugivores. [See p. 1196](#)

From our discussion of interactions between species that benefit both, we move to a type of interaction that benefits neither: competition. This type of interaction is widespread because it can arise wherever two or more species require the same resources.

56.4 What Are the Outcomes of Competition?

The antagonistic interactions can be quite attention-getting; the scene of a lion stalking a gazelle is almost emblematic of the African savanna. But at the same time a predator is interacting with its prey, it may also be interacting with other predators that hunt the same prey species. Lions are not the only predators of gazelles; cheetahs, hyenas, and even crocodiles hunt and kill gazelles, potentially reducing the supply available for lions.

Whenever any resource is not sufficiently abundant to meet the needs of all the organisms with an interest in that resource, organisms must compete with one another to gain enough of that resource to survive. Competition not only influences the evolution of species, but also plays an important role in determining the structure and composition of communities, as we will see in the next chapter.

Competition is widespread because all species share resources

Virtually no species enjoys exclusive access to any given resource; the vast majority must share at least some resources with other species. As we saw in Section 55.3, populations do not grow indefinitely, largely because resources are limited. In the absence of sufficient resources, individuals in the population compete for those resources. Such **intraspecific competition**—competition among individuals of the same species—may result in reduced growth and reproductive rates for some individuals, may exclude some individuals from better habitats, and may cause the deaths of others. **Interspecific competition**—competition among individuals of different species—affects individuals in much the same way. In addition, it can influence the persistence and evolution of species.

The *principle of competitive exclusion* holds that no two species can long coexist sharing the same limiting resource. If one species can prevent all members of another species from utilizing a resource, the inferior competitor may go locally extinct, a result called **competitive exclusion**. In other cases, selection pressures resulting from interspecific competition cause changes in the ways in which the competing species use the limiting resource. If those changes allow them to coexist, the result is called **resource partitioning**.

Whether it is interspecific or intraspecific, competition occurs by two major mechanisms. **Interference competition** occurs when a competitor interferes with another competitor's access to a limiting resource. **Exploitation competition** occurs when a limiting resource is available to all competitors and the outcome of competition depends on the relative efficiency with which the competitors use up the resource.

Interference competition may restrict habitat use

Interference competition can take many forms. A graphic example involves the desert ant *Conomyrma bicolor* and the honeypot ant *Myrmecocystus mexicanus*. These two ant species occupy the same type of habitat—arid areas containing little vegetation—and feed on similar foods—the sugary excretions of aphids and other sap-feeding insects and occasional arthropods, none of which is in great supply. When *C. bicolor* workers find the entrance of a honeypot ant nest, they pick up small stones in their mandibles, carry them to the rim of the nest opening, and drop them down the hole—up to 200 stones in a 5-minute interval. This activity is enough to stop the honeypot ants from going out foraging. Some honeypot ant colonies, under constant stone-dropping attack for several weeks, may be almost entirely deprived of food.

Even microorganisms interfere with one another's use of resources. In the highly structured environment of the rhizosphere, or “root-world,” of the soil, competitive interactions can be locally intense. Many soil bacteria produce substances that subdue their microbial competitors. Actinomycetes, for example, produce chemicals that interfere with essentially every life process in a bacterium. Many of the chemicals these remarkably well-defended microbes produce to defeat their competitors are used as antibiotics by mutualistic partners, such as the bark beetles described in Section 56.3, as well as in human pharmacology.

Exploitation competition may lead to coexistence

Exploitation competition may lead to coexistence, provided that the species relying on the same resource evolve ways to divide up, or partition, the resource. Resource partitioning can lead to the formation of **guilds**: groups of species that exploit the same resource, but in slightly different ways, making the resource less likely to be preempted. For example, in many Rocky Mountain communities, at least three species of bees consume the nectar of the shindagger agave (*Agave schottii*). The three bee species differ in where and when they collect shindagger nectar. Honey bees tend to forage in places with the greatest num-

bers of shindagger flowers, bumble bees in places with intermediate numbers of flowers, and carpenter bees where flowers are few and far between. Honey bees also tend to be most active when nectar output is greatest. With their larger nests and greater numbers of offspring to support, honey bees require greater efficiency and greater energy intake. Foraging sites that are not worth their while are left to the other bees.

Sometimes organisms respond to competition by leaving their competitors behind and finding new resources. Robert Denno examined a guild of seven sap-sucking insects called planthoppers living on salt marsh grass in marshes in New Jersey. Six of the seven species partition the resource by feeding on different parts of the plant or by feeding at different times during the season. All but one of the species are wingless and cannot fly. Whenever conditions become crowded in a particular patch of salt marsh grass, the seventh species—the only one with functional wings—flies away to find a new patch in which to feed.

Sometimes individuals within a species display different behaviors or morphologies depending on whether they are competing for resources with another species. Darwin remarked in *The Origin of Species* that “Natural Selection leads to divergence of character; for more living beings can be supported on the same area the more they diverge in structure, habits, and constitutions.” This “divergence of character,” today called **character displacement**, is most dramatic in cases in which the morphological attributes of a species vary depending on the presence or absence of a competitor. In some of the islands of the Galápagos archipelago, certain cactus species are pollinated exclusively by finches (**Figure 56.15**). On other islands, a carpenter bee (*Xylocopa darwini*) competes with the finches for cactus nectar; the birds consequently feed more heavily on seeds and insects. On the islands where bees are absent, finches feed on nectar more often, and have significantly smaller wingspans, than finches on

islands where they share cacti with bees. On the bee-free islands, a smaller wingspan means a smaller body size, which allows the birds to reach the nectar of the cactus flowers more easily.

Species may compete indirectly for a resource

Species may compete indirectly for a resource even when they are not present in the same habitat at the same time. Sometimes a species so alters the quality of a resource that it is rendered less usable by other species that may encounter it afterward. For example, feeding by sap-sucking leafhoppers on potato plants early in the growing season can cause leaf curling and chlorosis (loss of chlorophyll); potato beetles that consume these damaged leaves later in the growing season suffer reduced growth and survival rates. Even though these two herbivores do not feed at the same time, one species influences the use of the shared food resource by its competitor.

Consumers may influence the outcome of competition

Indirect competition can also result when two species share a common predator. For example, the parasitoid wasp *Venturia canescens* is a consumer of two different species of caterpillars that infest stored food products such as flour: the Indianmeal moth caterpillar (*Plodia interpunctella*) and the Mediterranean flour moth caterpillar (*Ephesia kuehniella*). The two species can coexist in a flour bin, but when the wasp is present it preferentially attacks and kills the flour moth caterpillars. Thus, in the presence of the wasp, the competitive balance between the two caterpillar species is altered in the meal moth’s favor. This type of competition is indirect because the outcome of competition depends not on how the two competitors utilize the shared resource, but on how the two competitors interact with a shared predator.

Competition may determine a species’ niche

Competition is important in determining where a species can be found. A species’ **niche** is the set of physical and biological conditions it requires to survive, grow, and reproduce. Thus a

56.15 Competition with Carpenter Bees Influences Finch

Morphology On islands in the Galápagos archipelago where finches are the sole pollinators of cactus flowers, a small wingspan increases their ability to negotiate the flowers. On islands where carpenter bees compete with finches for cactus nectar, the birds have a larger wingspan and can also feed on other foods.

species' niche is partly defined by the resources available in the environment. Although a species might be physiologically able to live under a wide range of resource conditions, competitors may restrict its use of resources in a particular location. Thus every species has a **fundamental niche**, defined by its physiological capabilities, and a **realized niche**, defined by interactions with other species.

Two species of barnacles, the rock barnacle (*Semibalanus balanoides*) and Poll's stellate barnacle (*Chthamalus stellatus*), compete for space on the rocky shorelines of the North Atlantic Ocean (**Figure 56.16**). The planktonic larvae of both species settle in the intertidal zone and metamorphose into sessile adults. The smaller stellate barnacles generally live higher at higher levels in the intertidal zone, where they face longer periods of exposure and desiccation (drying out) than do rock barnacles. There is little overlap between the areas occupied by adults of the two species. What explains their distinct distributions in the intertidal zone?

In a famous study conducted 50 years ago, Joseph Connell experimentally removed one or the other species from its characteristic zone and observed the response of the other species. Stellate barnacle larvae normally settle in large numbers throughout much of the intertidal zone, including the lower levels where rock barnacles are found, but they thrived at those lower levels only when rock barnacles were not present. The rock barnacles grow so fast that they smother, crush, or undercut the stellate barnacle larvae. In contrast, removing stellate barnacles from their spots higher in the intertidal zone did not lead to their replacement by rock barnacles; the rock barnacles are less tolerant of desiccation and fail to thrive there even when stellate barnacles are not around. The result of the competitive interaction between the two species is a pattern of *intertidal zonation*, with stellate barnacles restricted in their distribution by

competition and rock barnacles restricted in their distribution by their physiological limitations.

56.4 RECAP

Competition occurs when two or more species require a resource that is in limited supply. No two species can long coexist sharing a limiting resource. The outcome of competition may be competitive exclusion, in the form of local extinction, or coexistence, in the form of resource partitioning or character displacement.

- How does exploitation competition differ from interference competition? **See pp. 1198–1199**
- How can competition lead to character displacement? **See p. 1199 and Figure 56.15**
- Explain the difference between an organism's fundamental niche and its realized niche. **See pp. 1199–1200 and Figure 56.16**

The study of interactions among the species in a community is a large part of community ecology—the topic of the next chapter. Every kind of interaction we have studied in this chapter influences the nature and structure of communities. Competition helps determine which species persist and which go extinct, as well as dictating how many different species can be supported by a particular resource. Similarly, antagonistic interactions have important effects on the distribution and abundance of consumer and resource species, and the presence of mutualistic partners may dictate whether a particular species can exist in a particular community.

CHAPTER SUMMARY

56.1 What Types of Interactions Do Ecologists Study?

- Species interactions can be grouped into five categories. **Antagonistic interactions** benefit a consumer while harming the species that is consumed. A **mutualism** benefits both participants, whereas **competition** harms both. **Commensal** interactions benefit one participant with no effect on the other; **amensal** interactions have no effect on one participant but harm the other. **Review Figure 56.1, WEB ACTIVITY 56.1**
- The evolution of an adaptation in one species may lead to the evolution of an adaptation in a species with which it interacts, a process known as **reciprocal adaptation** or **coevolution**. A series of reciprocal adaptations can lead to a coevolutionary **arms race**.

56.2 How Do Antagonistic Interactions Evolve?

- Chemically defended animals often advertise their toxicity with **aposematism**, or warning coloration. **Review Figure 56.4**
- In **Batesian mimicry**, a palatable species mimics an unpalatable species. In **Müllerian mimicry**, two or more unpalatable species converge to resemble one another. **Review Figure 56.5**
- Some prey species avoid detection by means such as **crypsis** or **homotypy**. Others defend themselves by physical or chemical means. **Review Figure 56.6**
- Secondary metabolites are the principal defenses used by plants against herbivores, but many plants have physical defenses as well. Many herbivores have evolved resistance to plant secondary metabolites, and some have incorporated them into their own defenses against predators.
- The hosts of pathogenic microparasites fall into three classes: susceptible, infected, and recovered (and thus, in many cases, immune to another infection). Ectoparasites are less intimately associated with their hosts than are microparasites but can nevertheless affect host fitness.

56.3 How Do Mutualistic Interactions Evolve?

- Mutualistic interactions involve an exchange of benefits. Many mutualisms arise in environments where resources are in short supply.
- Reciprocal adaptations are most likely to arise when an increase in dependency on a partner provides an increase in the benefits realized from the interaction.

- Many mutualisms between plants and mobile animals involve an exchange of food for transport. In plant–pollinator interactions, animals that collect and transport pollen are rewarded with pollen, nectar, or other food rewards.
- Broad suites of floral characteristics that are attractive to certain types of pollinators exemplify **diffuse coevolution**. Some plant–pollinator mutualisms, however, are much more specific and exclusive. **Review Table 56.1 and Figure 56.11**
- Plants that depend on frugivores for seed dispersal must balance discouraging frugivores from eating fruits before the seeds are mature, attracting frugivores when the seeds are mature, and protecting the seeds from destruction in an animal's digestive tract.
- Some insects extract energy from plants by “farming” fungal species that possess the enzymes needed to digest plant material. Other mutualisms involve an exchange of food or housing for defense. **Review Figure 56.13 and 56.14, ANIMATED TUTORIAL 56.1**

56.4 What Are the Outcomes of Competition?

- Competition occurs whenever a resource is not sufficient to meet the needs of all individuals with an interest in that resource.
- Competition may result in local extinction of the inferior competitor, an outcome called **competitive exclusion**. Alternatively, selection pressures resulting from competition may change the ways in which different species use a limiting resource, an outcome called **resource partitioning**.
- Interference competition** occurs when an individual interferes with a competitor's access to a limiting resource. **Exploitation competition** occurs when a limiting resource is available to all competitors and the outcome depends on the relative efficiency with which competitors use up the resource.
- Competition may lead to **character displacement**, in which morphological attributes of a species vary geographically depending on whether a competitor is present or absent. **Review Figure 56.15**
- A species' **niche** is the set of physical and biological conditions it requires to persist. Although a species may be able to persist under a wide range of resource conditions (its fundamental niche), competitors may restrict its use of resources in a particular location (its realized niche). **Review Figure 56.16**

SELF-QUIZ

- Predation, herbivory, and parasitism are all examples of
 - antagonistic interactions.
 - mutualistic interactions.
 - commensal interactions.
 - amensal interactions.
 - competitive interactions.
- In a coevolutionary arms race, after a plant evolves a novel chemical defense against an herbivore,
 - the herbivore can be expected to go extinct.
 - the herbivore can be expected to disperse to new habitats.
 - the herbivore can be expected to evolve resistance to the plant's defense.
 - the plant can be expected to colonize new habitats.
 - the plant can be expected to outcompete all other plants in the same environment.
- Two organisms that use the same resources when those resources are in short supply are said to be
 - predators.
 - competitors.
 - mutualists.
 - commensalists.
 - amensalists.
- Damage caused to shrubs by branches falling from overhead trees is an example of
 - interference competition.
 - partial predation.
 - amensalism.
 - commensalism.
 - diffuse coevolution.

5. A hummingbird sips nectar from the flowers of a plant species and, in the process, pollinates those flowers. This interaction is best classified as
 - a. parasitism, because the hummingbird consumes the flower's nectar.
 - b. predation, because the hummingbird eats the plant's seeds.
 - c. commensalism, because the hummingbird benefits from consuming nectar and the plant is unaffected.
 - d. mutualistic, because the plant provides nectar for the hummingbird and the hummingbird transports pollen for the plant.
 - e. Not enough information is provided to classify this interaction.
6. Bright coloration that warns predators of prey toxicity is called
 - a. aposematism.
 - b. crypsis.
 - c. homotypy.
 - d. amensalism.
 - e. character displacement.
7. The type of mimicry in which a palatable species resembles a toxic species is called
 - a. Müllerian.
 - b. Batesian.
 - c. diffuse.
 - d. commensal.
 - e. homotypy.
8. Interference competition has been demonstrated to occur between
 - a. species of barnacles in the rocky intertidal zone.
 - b. species of ants in the deserts of North America.
 - c. species of soil bacteria that produce antibiotics.
 - d. all of the above
 - e. none of the above
9. One factor that can constrain the realized niche occupied by an organism is
 - a. immigration.
 - b. aposematism.
 - c. mimicry.
 - d. parasitism.
 - e. competition.
10. The principle of competitive exclusion states that
 - a. no two species can coexist unless they are sharing the same resource.
 - b. no two species can long coexist if they are sharing the same limiting resource.
 - c. if two species are sharing the same resource, one will always go extinct.
 - d. competition between two species always results in character displacement.
 - e. none of the above

FOR DISCUSSION

1. Many species interact, but not all interactions result in coevolution. How could you demonstrate that a particular plant has coevolved with a particular insect? What other explanations might account for adaptations in the plant that reduce the effect of a specific insect herbivore?
2. Aposematism is defined here as warning coloration, but warning colors would only be effective in deterring predators that use vision to find their prey. What other kinds of warning signals do you think might have evolved in interactions involving predators that rely on sensory cues other than vision? How would you investigate whether such signals exist?
3. Many ectoparasites are highly specific and feed on only a narrow range of host species. What do you think happens to host-specific parasites when their hosts go extinct? Should the parasites of an endangered species also be targets for conservation?
4. Even though nectar serves no function in the life of a plant other than to attract and reward pollinators, occasionally pollinators such as honey bees are poisoned by plant nectar. Why do you think some plants produce toxic nectars? Under what circumstances do you think toxic nectars would evolve?

ADDITIONAL INVESTIGATION

Like the Southern pine beetles (see Figure 56.13), the mountain pine beetle (*Dendroctonus ponderosae*) attacks pine trees with the help of a symbiotic fungus that infects the host tree. In 2009, these beetles infested almost 4 million acres of pine forest across Montana, Wyoming, Colorado, Idaho, Utah, Oregon, and

Washington. How would you determine which pine trees are susceptible to mountain pine beetle attack? How could the fact that this beetle has a symbiotic partner affect approaches for managing the outbreak?

Dead reckoning

In March 1996 the body of an apparent suicide victim was discovered under the bushes near the railroad tracks in Cologne, Germany. The corpse was badly decomposed, and most of the abdominal organs had disintegrated completely. When an autopsy was performed, masses of maggots—fly larvae—about 8 mm long were found in what remained of the body cavity, and the leathery patches of dried skin were almost totally covered with a layer of pale yellow eggs. When he examined the body, Mark Benecke, a forensic entomologist, was able to recover a single adult fly, which he identified as *Piophilidae casei*, also known as the cheese skipper.

The community of species that colonizes a human corpse is diverse, and its composition varies predictably over time as decomposition progresses. Among the many insect species that infest dead bodies, cheese skippers are latecomers—female cheese skippers do not find a corpse attractive until the proteins in the body begin to break down, typically after 1 to 3 months, depending on season

and locality. The abundance of *P. casei* eggs suggested to Benecke that the cheese skippers had undergone at least two generations in the decomposing corpse. Knowing that their development time from egg to adult ranged from 11 to 19 days under local weather conditions, he calculated that the first adult cheese skippers probably arrived and laid their eggs about 90 days after death, and that an additional 22 to 38 days would have been required for two generations to complete their development. Thus he calculated that death must have occurred between 112 and 128 days earlier. As it turned out, a 38-year-old woman had been reported missing about 4 months earlier; the estimated postmortem interval helped investigators to identify her as the suicide victim found by the railroad tracks.

Insects are found in decomposing corpses for many reasons. Some species, such as cheese skippers, consume the dead flesh; others, such as hide beetles, eat the hair and nails. Others prey on the insects consuming the corpse or eat their excrement and shed exoskeletons. Thus a dead body can support an entire community of organisms—one with complex connections among its inhabitants. Where and how an individual died can influence the composition of that community; bodies that are submerged, for example, are colonized by a different suite of insects than those that are buried in the ground.

Dead Reckoning Attracted by the odor of decaying flesh, bluebottle flies feed on the fur of a dead mole. The insect species on a decomposing corpse change in such a predictable fashion over time that forensic entomologists can estimate the time of death by identifying the species that are present.

Prairie Potholes These wetland communities occur in depressions in the prairie landscapes of midwestern North America. The potholes, formed when the glaciers of the last ice age receded, support communities characterized by many aquatic plant species, including sedges, bulrushes, and pondweeds.

What species occur where and when is the concern of community ecologists. The composition of communities can change in a predictable way over time and over space. The spatial scales of these changes can vary from a dead body in a patch of shrubbery to a patch of Amazonian rainforest, and the time scales can range from days to millennia. But the ecological processes affecting a community are similar whatever its scale. The study of the seemingly esoteric patterns of change in the composition of carrion communities has not only allowed ecologists to help find evidence that can identify a missing person or convict a murderer, but has added greatly to our understanding of ecological communities.

IN THIS CHAPTER we will investigate how energy flows through communities and how that flow influences their structure, complexity, and composition. We will investigate how communities are assembled over time and how they are reassembled after a disturbance. Finally, we will consider the relationships between species diversity, productivity, and stability in communities.

CHAPTER OUTLINE

- 57.1** What Are Ecological Communities?
- 57.2** How Do Interactions among Species Influence Community Structure?
- 57.3** What Patterns of Species Diversity Have Ecologists Observed?
- 57.4** How Do Disturbances Affect Ecological Communities?
- 57.5** How Does Species Richness Influence Community Stability?

57.1 What Are Ecological Communities?

An ecological **community** is a group of species that coexist and interact within a defined area. Although each species has unique interactions with the other species in its community, the community as a whole can be studied on the basis of the distribution of energy and biomass within it.

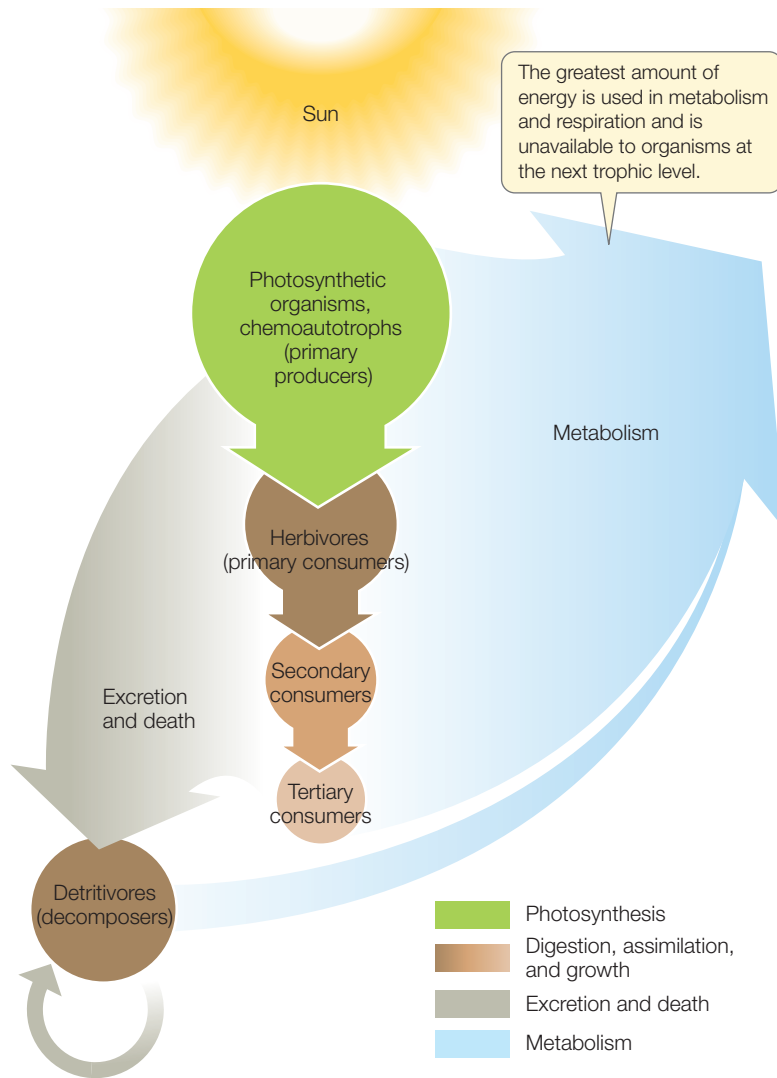

Communities vary greatly in size and scope. Whereas one ecologist might study the community of species inhabiting a dead body, another might study the community of species that inhabit Lake Superior, the largest of the Great Lakes. The boundaries defining a community are not always easy to recognize. The community of organisms within a pond, for example, is for the most part bounded by the borders of the pond. Pond species interact with one another to a far greater extent than with species outside the pond. The boundaries of other communities are not so clear-cut. For example, while prairie pothole communities (above left) may appear to be self-contained, many of their components originate far away. Seeds arrive at these relatively isolated wetlands via duck excrement; mallards and other ducks may consume, but not digest, seeds in one location and, in the 5–11 hours it takes for the seeds to move from one end of the digestive tract to the other, fly up to 1,400 km before depositing the seeds when they alight to feed again.

Communities may differ conspicuously in **species richness**—that is, in the number of species they contain. Even the same type of community may contain different numbers of species in different places. The number of plant species in prairie pothole communities, for example, may vary more than twofold across the upper Midwest. Although communities vary in size and complexity by orders of magnitude, ecologists have devised methods for quantifying basic properties of community structure and organization irrespective of their scale. These methods have revealed patterns that reflect underlying community assembly rules and general principles.

What determines how many species constitute a community in any particular place? One important factor is the amount of energy available to sustain organisms.

Energy enters communities through primary producers

Sunlight is the ultimate source of energy for most of Earth's communities. Sunlight makes photosynthesis possible, and photosynthesis, in the vast majority of communities, makes energy

available to other organisms in an edible form. All nonphotosynthetic organisms (*heterotrophs*) consume, either directly or indirectly, the energy-rich organic molecules produced by the plants and other photosynthetic organisms that get their energy directly from sunlight (*autotrophs*). Photosynthetic autotrophs, along with a handful of *chemoautotrophs* (organisms that obtain chemical energy from inorganic molecules in their environment), are known as **primary producers** (Figure 57.1).

57.1 Energy Flow through Trophic Levels Much of the energy of the biomass at each trophic level is lost (often as heat) to metabolism and respiration by the organisms at that level. In this diagram, the width of each arrow is roughly proportional to the amount of energy flowing through that channel. Arrows indicate directions of energy flow.

yourBioPortal.com

GO TO Web Activity 57.1 • Energy Flow through an Ecological Community

Gross primary productivity (GPP) is the rate at which all the primary producers in a particular community turn solar energy into stored chemical energy via photosynthesis. The energy that is accumulated is called **gross primary production**. (The terms “productivity” and “production” are often used interchangeably; *productivity* measures the rate of energy accumulation; *production* measures energy accumulation as a *product*.)

Not all GPP becomes available to heterotrophs, because primary producers use some of that energy for respiration and other metabolic processes. **Net primary productivity (NPP)** is the rate at which energy is incorporated into the primary producers’ bodies through growth and reproduction. Thus **net primary production** is the amount of primary producer **biomass** (weight of organic matter) available for consumption by heterotrophs. This relationship is described mathematically as

$$NPP = GPP - R$$

where R is the energy lost through respiration.

Consumers use diverse sources of energy

An organism’s **trophic level** indicates where in that sequence it obtains its energy (Table 57.1). Primary producers start the chain of trophic levels. At the next level are **primary consumers** — the herbivores that dine on the primary producers. Organisms that eat herbivores, called **secondary consumers**, are the next trophic level. Those that eat secondary consumers are *tertiary consumers*, and so on. The waste products and dead bodies of organisms provide another source of energy, as we saw at the

TABLE 57.1

The Major Trophic Levels

TROPHIC LEVEL	SOURCE OF ENERGY	EXAMPLES
Photosynthesizers (primary producers)	Solar energy	Green plants, photosynthetic bacteria and protists
Herbivores (primary consumers)	Tissues of primary producers	Termites, grasshoppers, gypsy moth larvae, anchovies, deer, geese, white-footed mice
Primary carnivores (secondary consumers)	Herbivores	Spiders, warblers, wolves, copepods
Secondary carnivores (tertiary consumers)	Primary carnivores	Tuna, falcons, killer whales
Omnivores	Several trophic levels	Humans, opossums, crabs, robins
Detritivores (decomposers)	Dead bodies and waste products of other organisms	Fungi, many bacteria, vultures, earthworms

57.2 Food Webs Show Trophic Interactions in a Community This food web for Isle Royale National Park, located on a large island in Lake Superior, includes only large vertebrates and the plants on which they depend. Even with these restrictions, the web is complex. The arrows show who eats whom.

opening of this chapter. Organisms that consume such materials are called *detritivores* or *decomposers* (see Figure 57.1).

Some organisms, called *omnivores*, feed on multiple trophic levels. Opossums, for example, are famously omnivorous. Investigators in Portland, Oregon, dissected the stomachs of road-killed opossums and found remains of mammals, birds, insects, earthworms, snails, fruits, bulbs, seeds, leaves, grass, pet food, and garbage, along with some items they couldn't even identify.

Although few organisms are as omnivorous as opossums, most species in a community eat and are eaten by more than one other species. A **food chain** depicts the linear sequence of who eats whom in a given community; food chains are interwoven in a **food web** (Figure 57.2). Most communities contain so many species interacting in so many different ways that it is impossible to enumerate (or even identify) all of the links. Nevertheless, simplified diagrams of food webs are useful in envisioning how energy flows through a community.

—yourBioPortal.com—

GO TO Web Activity 57.2 • The Major Trophic Levels

Fewer individuals and less biomass can be supported at higher trophic levels

One important way to characterize a community is by the distribution of energy and biomass within it. The flow of energy through a food web is governed by the physical laws that regulate energy transformations, foremost among which are the first and second laws of thermodynamics. Recall from Section 8.1 that the amount of energy in the universe is constant, and that when energy is converted from one form to another, part of it becomes unavailable to do work. As Figure 57.1 illustrates, at each trophic level energy is lost to metabolism and respiration. On average, only about 10 percent of the energy

of one trophic level is transferred the next, for a number of reasons:

- **Heat loss.** Organisms incorporate much of the energy they accumulate into biomass, but much more is used for respiration and other metabolic processes. That energy is dissipated as heat and is lost to the community.
- **Biomass availability.** Not all biomass can be ingested. Grazers routinely miss blades of grass; effective plant defenses prevent herbivory; prey can escape predators or leave the community.
- **Indigestibility.** Not all biomass ingested can be assimilated by consumers. Tree bark, for example, contains lignin and cellulose, which cannot be digested by most herbivores.

The overall transfer of energy from one trophic level to the next (which can be expressed as the ratio of consumer production to producer production) is called **ecological efficiency**.

Pyramid diagrams such as Figure 57.3A can be used to illustrate the proportions of energy transferred from each successive trophic levels and to compare those proportions among different communities. Pyramid diagrams can also be used to illustrate the amount of biomass or numbers of individuals found at each level (Figure 57.3B). Progressive energy loss through the inefficiencies of energy transfer puts limits on the number of trophic levels in a food chain or food web; largely for this reason, most communities support only three to five trophic levels. Furthermore, each successive trophic level tends to have fewer species, and the species at each level tend to have lower reproductive rates, smaller populations, and larger body sizes.

Productivity and species richness are linked

Just as the diversity and complexity of trophic levels tend to be positively correlated with the amount of energy available to them, the species richness of a community tends to be positively correlated with its productivity, up to a point. A number of factors that influence productivity, and thus species richness, vary among communities.

The most obvious variation that influences productivity is energy input. The amount of solar energy reaching Earth's surface

57.3 Energy and Biomass Distributions Pyramid diagrams allow ecologists to compare (A) patterns of energy flow through trophic levels in different communities and (B) the amount of biomass present at the different trophic levels.

57.4 Species Richness Peaks at Intermediate Productivity The number of rodent species living in ecosystems of varying productivity in the Gobi Desert exemplifies a pattern in which species richness increases only up to a certain point. Beyond that point, it can actually decline with productivity.

varies by latitude, as we saw in Figure 54.1. The ability of plants to photosynthesize, however, depends not only on the supply of energy from the sun, but also on the supply of water and nutrients. The species richness of trees across different regions of North America, for example, can be best predicted not by measuring incoming solar radiation, but by measuring an ecological attribute of those regions called *annual evapotranspiration*: the amount of water released from the land surface by evaporation from streams, lakes, and soil and by transpiration from plants. The annual evapotranspiration of a region is measure of the amount of water available to the organisms living there.

The number of species in a community increases with productivity only up to a point, however; if productivity increases beyond that point, species richness may actually decline (**Figure 57.4**). Why should that be? As local productivity increases, so does the number of individuals the local habitat can support (its carrying capacity). Thus populations can grow larger, and larger population sizes should reduce the risk of species extinction. Why, then, should species richness decrease when productivity is very high?

One hypothesis postulates that interspecific competition becomes more intense when productivity is very high, resulting in competitive exclusion of some species (see Section 56.4). This hypothesis is supported by the results of a long-term experiment at the Rothamsted Experiment Station in England, begun in 1857 and still ongoing. Fertilizer has been added regularly to selected plots of land to increase their productivity, and fertilized and unfertilized plots have been monitored continuously. Over 150 years, the number of plant species in the unfertilized plots has remained roughly constant, whereas that number has declined in the fertilized plots, supporting the premise that species richness can decline when productivity rises.

57.1 RECAP

An ecological community is a group of species that coexist and interact within a defined area. Net primary production—the amount of biomass that primary producers make available to heterotrophs through photosynthesis—is an important factor determining the species richness and number of trophic levels in a community.

- Explain the difference between gross primary productivity and net primary productivity. **See p. 1205**
- Describe three trophic levels that might appear in a food web. **See pp. 1205–1206, Table 57.1, and Figure Figure 57.2**
- What is a typical distribution of energy among the trophic levels of a community? **See pp. 1205–1206 and Figures 57.1 and 57.3**

Although energy and biomass distributions reveal much about the structure and dynamics of ecological communities, they reflect primarily the abiotic mechanisms that influence the community. In the next section we will see how the species interactions described in Chapter 56 shape community structure.

57.2 How Do Interactions among Species Influence Community Structure?

All of the interaction types discussed in Chapter 56, and especially the antagonistic interactions, have a strong influence on an ecological community. Species are not identical bags of biomass through which energy flows. Species in one part of a food web can affect many other species without necessarily eating them.

Species interactions can cause trophic cascades

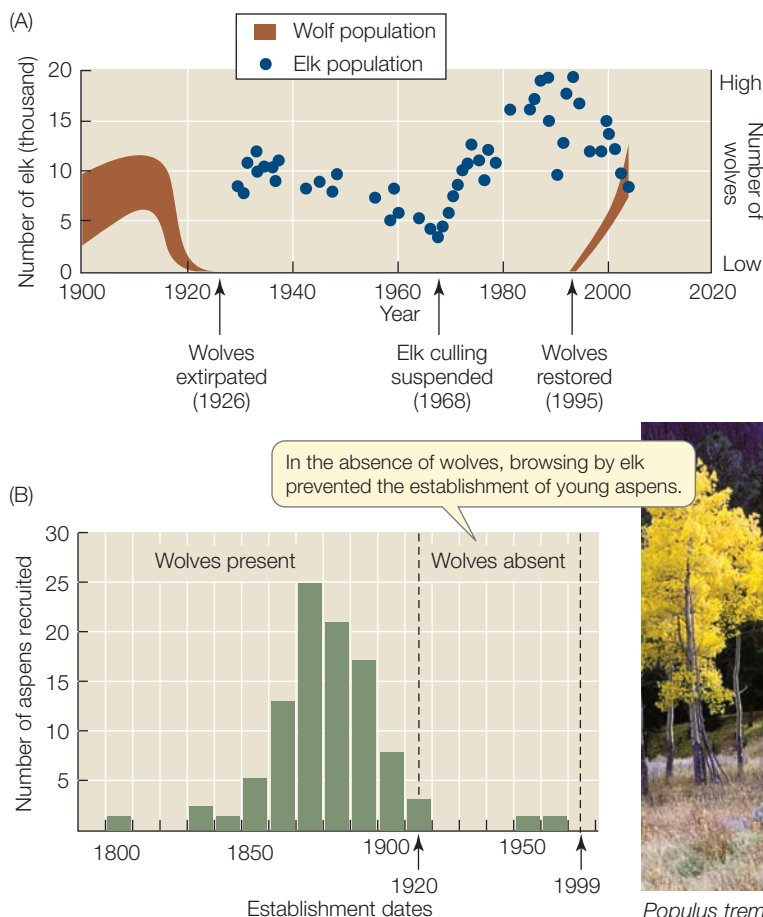

The interactions of a single consumer with other species in its community can cause a progression of indirect effects across successive trophic levels, a pattern called a **trophic cascade**. The reintroduction of wolves into Lamar Valley, in Yellowstone National Park, initiated just such a pattern.

The food web in Yellowstone National Park is complex. Wolves in the park feed on moose, pronghorn, mule deer, elk, bison, and bighorn sheep. Although they share these prey with

coyotes, mountain lions, and grizzly and black bears, wolves exert particularly strong effects on the park community's structure and dynamics, as demonstrated by the effects of their absence during most of the twentieth century. By 1926, unrestricted hunting had eliminated wolves from the park community.

Annual censuses of elk were initiated by park managers in 1920. To prevent elk from exceeding the park's carrying capacity, the park service culled elk herds (that is, they selectively killed some members of the herds) until 1968, when, in response to public pressure, the culls were stopped. When the culling ended, the elk population rapidly increased (**Figure 57.5A**). The elk browsed aspen trees so intensely that no young trees were added to the population after 1920 (**Figure 57.5B**). The elk also severely browsed streamside willows, with the result that beavers, which depend on willows for food, were nearly exterminated from Lamar Valley. In regions of the park where elk were absent, however, aspen and willow trees flourished. This observation suggested that the decline of the trees elsewhere in the park was indeed due to elk browsing, rather than to climatic conditions or some other factor.

In 1995, after a 70-year absence, park managers reintroduced wolves to Yellowstone, and their population grew rapidly. The wolves preyed primarily on elk. The elk population of Lamar Valley dropped, and elk avoided the aspen groves, where they were especially vulnerable to wolf predation. Young aspen began to grow, willows regrew along streams, and the number of beaver colonies increased from one in 1996 to seven in 2003. Thus the presence or absence of a single predator influenced not only populations of its prey, but also the structure of the vegetation and populations of other species that depend on that vegetation.

57.5 Wolves Initiated a Trophic Cascade (A) Number of elk and relative size of the wolf population in Wyoming's Yellowstone National Park. Once the wolves were gone, the elk population increased to the point where the young aspen trees were seriously overgrazed. (B) Aspen establishment in the presence and in the absence of wolves. With overgrazing by elk, young trees were not recruited; the photo shows a resulting stand of only mature trees.

Populus tremuloides

Herbivores, too, can have indirect effects on other trophic levels, to produce an interaction cascade. The savannas of central Kenya are dominated by large grazing mammals such as zebras, eland, elephants, Grant's gazelles, giraffes, buffaloes, and hartebeests. A team of investigators used *exclosures* (areas protected by a barrier, such as a fence, designed to keep organisms out) to investigate the influence of these grazers on the savanna community. They created six exclosures and compared community structure within the exclosures with that in paired sites where large mammals could graze freely. Over 19 months of monitoring, they found that trees, beetles, and an insectivorous lizard species were all more abundant within the exclosures. The elimination of grazing increased the abundance of trees, which in turn increased the number of beetles by providing more food and habitat, which in turn increased the number of lizards, which feed preferentially on beetles.

Interaction cascades can be initiated by the behaviors of species as well as by their diets. Beavers preferentially cut down some species of trees to build their dams; by so doing, they alter the composition of the vegetation. In addition, the beaver dams create wetlands, meadows, and ponds that provide habitat for species that would otherwise not be able to live in the area. Organisms that build structures that alter existing habitats or create new habitats are called **ecosystem engineers**.

Keystone species have wide-ranging effects

A species that exerts an influence on a community disproportionate to its abundance is called a **keystone species**. Keystone species influence both the species richness and the number of trophic levels in a community. The ochre sea star (*Pisaster ochraceus*), which lives in rocky intertidal zones on the Pacific coast of North America, is a good example. Its preferred prey is the mussel *Mytilus californianus*. In the absence of sea stars, these mussels crowd out other organisms in a broad belt of the intertidal zone. By consuming mussels, *P. ochraceus* creates bare spaces on the rocky substratum that are taken over by a variety of other species (**Figure 57.6**).

In a classic experiment, Robert Paine of the University of Washington demonstrated the disproportionate influence of ochre sea stars on species richness by removing them from selected sites repeatedly over a 5-year period. Two major changes occurred in the areas where sea stars were absent. First, the lower edge of the mussel bed extended farther down into the intertidal zone, showing that sea stars are able to eliminate mussels completely in areas that are submerged most of the time. Second, and more dramatically, 28 species of animals and algae disappeared from the sea star removal sites. Eventually only *M. californianus*—the dominant competitor for space in the community—occupied the entire substratum. Through its effect on competitive relationships, predation by the sea star determines how many species can thrive in its rocky intertidal community.

Species other than consumers can be keystone species. A plant species that serves as food for many different animals can also be a keystone species. Fig trees in tropical forests produce fruits several times every year, so their fruits are abundant at times when few, if any, other trees are fruiting. Dozens of frugi-

57.6 Some Sea Stars Are Keystone Species Ochre sea stars (*Pisaster ochraceus*) have harvested all the mussels from the lower parts of these rocks on the Olympic Peninsula of Washington. By consuming mussels, the sea star creates bare spaces on the rocks that are occupied by a variety of other intertidal species.

vores depend on figs when no other fruits are present. Fig-eating animals include fruit bats, parrots, toucans, pigeons, flycatchers, trogons, orioles, rodents, howler monkeys, and even fish, which eat figs that fall into nearby streams. All of these animals provide prey for a diverse community of predators. Moreover, the trunks of fig trees provide habitat for several thousand species of insects, reptiles, rodents, and birds. Without fig trees, rainforest communities around the world would be profoundly diminished in species richness.

57.2 RECAP

Some interactions between consumers and other species result in a trophic cascade of indirect effects on species at successive trophic levels. Keystone species are species with especially strong effects on the species richness and number of trophic levels in communities.

- Describe an example of a consumer whose interactions with other species cause indirect effects across trophic levels.
- What are some of the ways in which keystone species can affect other species in their communities?

See p. 1209

We have seen how certain keystone species influence the overall species richness of their communities. But species richness is only one measure of community diversity. The next section takes a closer look at other ways in which ecologists measure species diversity.

57.3 What Patterns of Species Diversity Have Ecologists Observed?

Communities clearly vary in their diversity, both geographically on scales ranging from local to global, and over time on scales ranging from a day to centuries. Comparing the diversity of two or more communities can be challenging because diversity has many different components depending on the scale at which it is measured:

- **Alpha diversity** is diversity *within* a single community or habitat.
- **Beta diversity** is *between-habitat* diversity, a measure of the change in species composition from one community or habitat to another.
- **Gamma diversity** is the *regional* diversity found over a range of communities or habitats in a geographic region.

Although the two communities have the same species richness, community A has a more even distribution of species, and is thus considered more diverse than community B.

A community's diversity can be measured with a diversity index

The most straightforward way to quantify the alpha diversity of a community is simply to count the number of species present in a sample (that is, the species richness). The larger the area that is sampled, the greater the likelihood that rare species in the community will be found and that the resulting assessment of its species richness will be accurate.

To say that two communities of the same size have the same species richness tells only part of the story, however. Imagine that we take samples of 12 individuals in each of two communities. Our sample from community A contains 3 individuals of each of 4 species (an even distribution of individuals). Our sample from community B, however, contains 9 individuals of one species and only 1 individual each of the other 3 species (an uneven distribution). Even though the species richness of the two communities is the same (4), community B is considered less diverse because the less abundant species are encountered infrequently compared with the single most abundant species (**Figure 57.7**). Thus estimates of diversity should account for both species richness and species evenness.

Ecologists have devised mathematical formulas to quantify diversity that take both species richness and species evenness into account. One widely used measure is the **Shannon diversity index**, based on a mathematical expression of the certainty with which the next item sampled in a series can be predicted. If, for example, we picked individuals from community B in Figure 57.7 at random, we would be fairly certain which species would be picked first, second, third, and so on: most of the time, it would be the most abundant species. The Shannon diversity index (H) describes diversity as a measure of that certainty. The higher H is, the lower would be our certainty about the species composition of our sample and, thus, the greater the diversity of the community. In other words, when we know that the abundance of a particular species is high, we can be reasonably certain that we are likely to collect that species in a random sample.

We can calculate H in three steps:

- Determine the proportion of the total number of individuals in the community that are in each species (p_i) and multiply that proportion by its logarithm
- Sum the values obtained for all species in the community
- For mathematical reasons, multiply the result by -1

In algebraic notation, this calculation is written as

$$H = -[(p_1 \ln p_1) + (p_2 \ln p_2) + (p_3 \ln p_3) \dots (p_n \ln p_n)]$$

Estimating the alpha diversity of a single community with the Shannon diversity index requires only that we know the total number of individuals collected in a sample and the number of species in the sample. But describing the species diversity of a

Figure 57.7 Species Richness and Species Evenness Contribute to Diversity These two hypothetical mushroom communities are the same size (12) and have the same species richness (4) but differ in species evenness. The more even distribution results in greater diversity.

geographic region that comprises multiple communities requires a different approach. Recall that measures of beta diversity estimate the change in species composition from one community to another. **Sorenson's index** (C_s) is one such measure, calculated

$$C_s = \frac{2j}{a+b}$$

where $2j$ is twice the number of species found in both communities, a is the number of species in the first community, and b is the number of species in the second community.

Gamma diversity—the overall diversity across a geographic region containing many different communities—can be used to make comparisons of diversity among regions. Gamma diversity is equivalent to the alpha diversity of each community combined with the beta diversity between the communities.

Partitioning diversity within a community, between communities, and across an entire region can provide insights into the ecological characteristics of the species making up those communities as well as the processes by which those communities were assembled. High beta diversity, for example, shows that few species are shared between the communities being compared, suggesting that those communities consist mostly of specialists, species with unique habitat requirements, or species with poor dispersal abilities.

A study of diversity patterns in an agricultural area of southern England demonstrates how these three measures of diversity estimates are applied at different scales. Investigators sampled plants and macroinvertebrates in three types of freshwater communities—rivers, ponds, and ditches—in an area of English countryside. Rivers had high species richness (i.e., high alpha diversity), but most rivers in the area contained the same assortment of species, so beta diversity, from river to river, was

low. In contrast, the ponds displayed a wide range of variation in species richness (i.e., the ponds, with high beta diversity, were more different from one another in species composition than the rivers were). Thus the ponds contributed more to gamma diversity—the overall diversity of the area—than the rivers did because they contained more unique or rare species. Surprisingly, the ditches, many of which contained water for only a short time, had the lowest alpha diversity (the fewest species overall) of the three community types, but many of the species found in ditches were found nowhere else in the area, including insects that live only in temporary bodies of water (including a very rare water beetle). Ponds and ditches, despite being relatively species-poor, contributed disproportionately to regional diversity (i.e., gamma diversity) because the few species they supported were found nowhere else in the region.

Latitudinal gradients in diversity are observed in both hemispheres

It has long been known that diversity varies with latitude. About 200 years ago, the German explorer and naturalist Alexander von Humboldt spent 5 years traveling around Latin America. He remarked in the account of his voyages that “the nearer we approach the tropics, the greater the increase in the variety of structure, grace of form, and mixture of colors, as also in perpetual youth and vigour of organic life.” Humboldt would not have been surprised to learn that, if he had sailed toward the poles, the diversity he observed would have decreased. These latitudinal gradients in diversity have been observed in a wide variety of taxa, including birds, mammals, and insects (**Figure 57.8**).

Although most ecologists agree that latitudinal gradients in diversity exist, there is less consensus as to why they exist. At least four hypotheses have been advanced to account for latitudinal gradients in diversity:

57.8 Latitudinal Gradients in Diversity Among swallowtail butterflies (*Papilionidae*), species diversity decreases with latitude both north and south of the equator. Similar latitudinal gradients of diversity have been observed in many other taxa.

- The *time hypothesis* argues that organisms in tropical regions have had more time to diversify under relatively stable climatic conditions than have more temperate regions.
- The *spatial heterogeneity hypothesis* suggests that tropical regions have high spatial heterogeneity—more different types of microclimates, vegetation, soils, and so forth—and thus contain more different habitats and many more species.
- The *specialization hypothesis* attributes latitudinal gradients in diversity greater of biological competition in the tropics, which lead to narrower niches and more species.
- The *predation hypothesis* proposes that predation intensity is greater in the tropics (and thus conflicts with the specialization hypothesis). Where predation is high, it argues, prey populations are held to levels so low that interspecific competition never comes into play, and rare species can persist.

Why can't ecologists agree on the mechanism underlying latitudinal gradients in species diversity? Corroborative evidence can be found for each of these hypotheses, varying with taxon, locality, and scale. It may be that multiple factors are responsible for this widespread ecological pattern.

The theory of island biogeography suggests that species richness reaches an equilibrium

While latitudinal gradients prevail on a global scale, other factors influence species diversity within any latitudinal band. In the West Indies, for example, small islands tend to have fewer species of butterflies than large islands, irrespective of latitude. Furthermore, oceanic islands generally have fewer species, irrespective of taxon, than continental areas of comparable size. This **species–area relationship** is a well-established mathematical relationship between the size of an area of habitat and the number of species that area contains. The biologist Edward O. Wilson was struck by this relationship, which he encountered through

his exhaustive collection of ant species from all over the world. With Robert MacArthur, Wilson developed the theory of **island biogeography**. They based their theory on just two processes: the immigration of new species to an island and the extinction of species already present on that island (**Figure 57.9A**).

The premise of island biogeography is that the number of species on an island (or in another geographically defined and isolated area) represents a balance, or equilibrium, between the rate at which species immigrate to the island and the rate at which resident species go locally extinct. The rate of immigration is determined in part by the number of species in the area providing the immigrants, known as the **species pool**. In the case of oceanic islands, the species pool comprises all the species on the nearest continent. Not all species that reach the island will persist, however. The more species there are on an island, the higher the likelihood that any one of those species will go extinct.

Rates of immigration and extinction are influenced by two other factors:

- *Distance of the island from the species pool.* The farther the island from the source of immigrants, the fewer species will successfully make the trip and the lower the immigration rate.
- *The size (area) of the island.* The smaller the island, the fewer resources it provides, and the higher the extinction rate. Larger islands provide greater habitat diversity and can sustain larger populations (which in general have lower extinction rates than small populations).

57.9 MacArthur and Wilson's Theory of Island Biogeography

(A) The rate of arrival of new species and the rate of extinction of species already present determine the equilibrium number of species on an island. (B) These rates are affected by the size of the island and its distance from the mainland.

INVESTIGATING LIFE

57.10 Testing the Theory of Island Biogeography

By experimentally removing all the arthropods on four small mangrove islands, Simberloff and Wilson were able to observe the rates at which arthropods recolonized the islands and compare these data with the predictions of island biogeography theory.

HYPOTHESIS Defaunated islands will be rapidly recolonized and will achieve about the same number of species that were present prior to defaunation.

METHOD

1. Census the terrestrial arthropod species on 4 small (11–25 m²) mangrove islets.
2. Erect scaffolding and tent the islets. Fumigate with methyl bromide, a chemical that kills arthropods but does not harm plants.

3. Remove tenting. Monitor recolonization for the following 2 years, periodically censusing terrestrial arthropod species.

RESULTS

Recolonization was fastest on the closer islands, slowest on the one farthest from the mainland. Two years after defaunation, each island had about the same number of species it had before the experiment.

CONCLUSION The data support the premise that an island supports a certain equilibrium number of species.

FURTHER INVESTIGATION: This experiment assessed only arthropod species, and its duration (2 years) was brief in terms of evolutionary time. What experiments might you conduct to assess some of the broader predictions of the theory?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

At some point, the number of species arriving from the source and the number of resident species going extinct should balance, and the number should remain stable at this balance point—the *equilibrium number of species* (Figure 57.9B).

Wilson and his student Daniel Simberloff devised an ingenious experiment to test the theory of island biogeography. They used four small, isolated clumps of red mangrove (*Rhizophora mangel*), 11–18 m in diameter, in the Florida Keys. These mangrove islands were small enough that Simberloff and Wilson could count the arthropod species on each one, then enclose it in a tent and gas it with methyl bromide to kill all the arthropods. After defaunation, Simberloff and Wilson monitored and tracked recolonization of the islands by arthropods (Figure 57.10). Recolonization was generally rapid, but was slowest on the island farthest from the mainland, as predicted by the theory of island biogeography. Furthermore, all of the islands eventually supported roughly the same number of species that they had before defaunation—again, as predicted.

The theory of island biogeography has been widely accepted since Simberloff and Wilson's landmark study. In addition, it has been retrospectively tested by studies of recolonization after major disturbances that serve as "natural experiments." For example, in August 1883, the island of Krakatau was devastated by a series of volcanic eruptions that destroyed all life on its surface. After the lava cooled, plants and animals from Sumatra to the west and Java to the east recolonized Krakatau. By 1933, the island was again covered with a tropical evergreen forest, and 271 species of plants and 27 species of resident land birds were found there (Table 57.2). Today the numbers of plant and bird species are not increasing as fast as they did between 1900 and 1930, but colonizations and extinctions continue, as predicted by the theory of island biogeography.

The theory of island biogeography is so robust that it can be applied equally well to *habitat islands*—isolated patches of suitable habitat surrounded by extensive areas of unsuitable habitat. Thus an oasis in the desert or a prairie pothole surrounded by housing subdivisions may acquire an equilibrium number of species in much the same way an oceanic island does.

TABLE 57.2		
Number of Land Plant and Resident Land Bird Species on Krakatau		
TIME ^a	NUMBER OF PLANT SPECIES	NUMBER OF BIRD SPECIES
1883 (<i>t</i> = 0)	0	0
1886 (<i>t</i> = 3)	26	0
1897 (<i>t</i> = 14)	64	8
1908 (<i>t</i> = 25)	115	13
1920 (<i>t</i> = 37)	184	27
1928 (<i>t</i> = 45)	214	27
1934 (<i>t</i> = 51)	271	29

^a Time is given as the year, followed by the number of years since the volcanic eruption that destroyed all life on the island.

57.3 RECAP

Species diversity encompasses both species richness and species evenness. It is highest in the tropics, decreasing in higher latitudes. Island biogeography theory states that species diversity on an island or other isolated habitat fragment represents a balance between immigration and extinction rates.

- Explain the concepts of alpha, beta, and gamma diversity. **See p. 1210**
- What is the difference between species richness and species evenness? **See p. 1210 and Figure 57.7**
- What factors influence the equilibrium number of species on an island, according to the theory of island biogeography? **See p. 1212 and Figure 57.9**

Droughts, fires, and volcanic eruptions are examples of ecological disturbances. The next section looks at the effects of such disturbances on ecological communities.

57.4 How Do Disturbances Affect Ecological Communities?

An ecological disturbance is any abiotic event that changes the probability of persistence of one or more species in an ecological community. Disturbances may remove some species from a community, but may open up space and resources for other species. The magnitude of the effect of a disturbance varies enormously. Some disturbances are limited to small areas—for example, a log carried by waves may crush algae and animals attached to rocks in an intertidal community. In contrast, hurricanes, forest fires, and volcanic eruptions can affect communities over hundreds or thousands of hectares. Although small-scale disturbances are far more frequent than large ones, a few large events may be responsible for most of the changes in a community. A single hurricane, for example, may fell more trees than years of “normal” storms.

A community’s history of disturbance may explain patterns of species diversity that would otherwise be puzzling. The sub-Antarctic Province Islands, located in the South Indian Ocean, provide an example. The climate of these islands is cool, with monthly average temperatures above freezing for only 6 months of the year. Precipitation is high, and gale force winds are not uncommon; the vegetation is primarily tundra. South African entomologist S. L. Chown, an expert on life in the Antarctic, compared the insect faunas on the four largest of these islands and found that the two largest, Marion and Kerguelen, housed fewer arthropod species (16 and 22, respectively) than the significantly smaller Cochons and Possessions (26 and 38).

Why do the species diversity patterns on these islands fail to conform to the theory of island biogeography? One possible explanation is the different geological histories of the islands. The two smaller islands have escaped extensive glaciation, and accordingly have been accumulating species over a longer time than have the larger islands. Thus, the theory of island biogeography notwithstanding, island area may not always be the best predictor of species diversity. Geological history—particularly the history of disturbances—is often a better predictor.

Succession is the predictable pattern of change in a community after a disturbance

How does a community reassemble itself after a disturbance, particularly one as massive as a glacier? The pattern of change in community composition following a disturbance is known as **succession**. The most common type of succession is *directional* succession, which is characterized by an orderly (or at least predictable) progression of community assemblages. Species come and go until a particular community—one that is capable of perpetuating itself under local climatic and soil conditions—persists for a relatively long time. This persistent stage is called the **climax community**.

Directional succession is easiest to observe after a disturbance strips away all preexisting living organisms and exposes a bare substratum; this type of directional change is known as **primary succession**. Disturbances such as glaciers, volcanic activity, and in some cases, floods can initiate primary succession.

Primary succession can be seen in the change in plant growth form and community composition following the retreat of a glacier in Glacier Bay, Alaska, over the last 200 years (**Figure 57.11**). The glacier scraped the landscape down to bare rock and left a series of *moraines*—gravel deposits formed where the glacial front was stationary for a number of years. No human observer was present to measure changes over the entire 200-year period, but ecologists have inferred the temporal pattern of succession by studying the vegetation on moraines of different ages. The youngest moraines, closest to the current glacial front, are populated with bacteria, fungi, and photosynthetic microorganisms that can support themselves on bare rock. Slightly older moraines farther from the glacial front have lichens, mosses, and a few species of shallow-rooted herbs, such as mountain avens (*Dryas octopetala*). Still farther from the glacial front, successively older moraines have shrubby willows, alders, and spruces.

57.11 Primary Succession As the community occupying a glacial moraine at Glacier Bay, Alaska, changes from an assemblage of pioneer plants such as *Dryas* to a spruce forest, nitrogen accumulates in the soil.

[yourBioPortal.com](#)

GO TO Animated Tutorial 57.2 • Primary Succession on a Glacial Moraine

tend to occur more frequently and progress more rapidly.

A typical sequence of secondary succession in eastern North America begins when forested land that had been cleared for agriculture is abandoned (**Figure 57.12**). The first plants to appear in old agricultural fields are fast-growing annuals such as pigweed, ragweed, and lamb's-quarter. These pioneer species are quickly replaced by more competitive biennials and perennials, such as milkweed, goldenrod, and thistles. Eventually, shrubby plants such as dogwood, eastern red cedar, and sumac become established, followed by tree species such as cottonwood, cherry, and red maple. Ultimately,

shade-tolerant trees, including beech and sugar maple, dominate the landscape. The beech-maple forest is the climax community for much of the region.

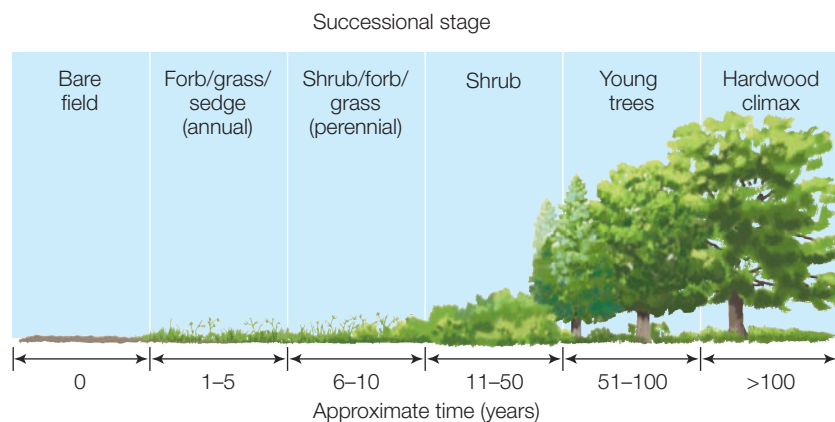

Directional succession, irrespective of where it takes place, is characterized by certain trends. In general, the colonizing species of early successional stages tend to be good dispersers with high intrinsic rates of reproduction (*r*-strategists). Early stages of succession are characterized by high productivity and simple food webs; most nutrients are present as detritus or in abiotic forms. As succession proceeds, nutrients accumulate in biomass, food webs become more complex, and abiotic sources of nutrients become less important. Species typical of late successional stages tend to be good competitors with relatively low intrinsic rates of reproduction (*K*-strategists).

Nitrogen is virtually absent from glacial moraines, so the plants that grow best on recently formed moraines at Glacier Bay are *Dryas* and alders (*Alnus*), both of which have nitrogen-fixing bacteria in nodules on their roots (see Figure 36.9). Nitrogen fixation by these plants improves the soil so that spruces can grow. Spruces then outcompete and displace the early colonists. If the local climate does not change dramatically, a climax community dominated by spruce trees is likely to persist for many centuries on old moraines at Glacier Bay.

Directional succession following a disturbance that some organisms, particularly those in the soil, survive is called **secondary succession**. Secondary successions are often initiated by human activities as well as by natural disasters. Generally easier to monitor than primary succession, secondary successions also

Both facilitation and inhibition influence succession

To some extent, the progress of succession depends on the activity of successive colonists, each of which modifies the environment in such a way as to facilitate colonization by other species. Predators are unlikely to colonize a habitat with no prey species, nor can primary consumers exist before

57.12 Secondary Succession Secondary succession is the process by which land that once supported an agricultural field can ultimately support a long-lasting climax community characterized by shade-tolerant trees.

plants are established. The fixation of nitrogen by *Dryas* and alders that allows spruces to become established in Glacier Bay (see Figure 57.11) is an example of such **facilitation**.

Although secondary succession is often described in terms of changes in plant species composition, colonization by plants is actually facilitated by heterotrophs. Often the first organisms to arrive on bare soil after a disturbance are detritivores, which process dead organic matter and release nutrients (especially nitrogen) and thus facilitate the establishment of plants. In a study of intensively burned 20-year-old pine plantations in northern Germany, the first organisms to colonize the burned forests were slime molds, liverworts, mosses, and mushrooms. These detritivores were followed by algae-feeding flies, fungus-feeding beetles, and moss-feeding springtails. Flowering plants such as fireweed moved in, at which point leaf-feeding insects appeared, soon followed by predaceous ground beetles and wolf spiders.

In other cases, the effect of early colonists is **inhibition**, rather than facilitation, of colonization by other species. Old-field species such as goldenrod and thistle produce root exudates that inhibit the germination and growth of potential competitors. Eventually, when these plants grow old and die, other plant species can become established.

Cyclical succession requires adaptation to periodic disturbances

Some patterns of succession are *cyclical*, rather than directional. In such cases, the climax community depends on periodic disturbance in order to persist. The lodgepole pine (*Pinus contorta*) forests that grow in the pumice plateau area of southern Oregon are maintained by periodic forest fires (Figure 57.13). In this fire-adapted community, fires return nutrients to the soil in the form of burned organic matter and provide proper conditions for seed germination. The cones of lodgepole pines are sealed shut by resins; only when they are subjected to high temperatures that melt the resins do they open and release their seeds. The lodgepole pine is attacked by *Dendroctonus ponderosae*, the mountain pine beetle, and is also prone to infection by a fungus, *Phaeolus schweinitzii*, which causes the roots and heartwood of the pines to rot. Trees that have lived long enough to experience and be scarred by a fire are much more likely to become infected by the fungus than are trees that have not been scarred. Fungus-infected, weakened trees are preferentially attacked by beetles. After a beetle outbreak, in which many fire-scarred mature trees are killed, the dead trees serve as potential fuel for a fire. The next fire frees up their nutrients for use by the remaining trees as well as new seedlings.

Heterotrophic succession generates distinctive communities

Plants play a vital role in most patterns of succession because, as autotrophs, they are the source of energy for the other organisms in the community. Successional changes, however, can take place without the participation of plants. Detritus-based communities—found in dung, carrion, or dead plants—undergo a

57.13 Some Communities are Adapted to Disturbance Forest communities dominated by lodgepole pine (*Pinus contorta*) are adapted to periodic fires. Fire removes mature trees weakened by pest infestation, revitalizes the soil, and provides essential conditions for seed germination and new growth.

series of changes known as **heterotrophic succession**. These changes differ from those in other types of directional succession. First, succession begins heterotrophically: energy resources are greatest when the habitat first becomes available to colonists and are depleted as succession takes place. There is no mechanism, such as photosynthesis, for generating more energy. Second, total biomass and species diversity decrease over time as the resource base declines. Third, these temporary habitats are not really self-contained, so predators can outnumber primary consumers (detritivores, in these communities) in apparent violation of the laws of thermodynamics.

Because the habitats in which heterotrophic succession occurs are so conveniently small, many patterns of heterotrophic succession have been thoroughly investigated. One such pattern is faunal succession in human corpses, as we saw at the opening of this chapter. M. G. Motter's 1898 study of 150 disinterments, followed by more recent studies on pig decomposition (after disinterments of human bodies for scientific purposes were discouraged), allowed for precise reconstruction of the temporal sequence of species in these communities.

There are three major stages of decomposition, each characterized by a distinctive faunal community. The first stage, *autolysis*, is characterized by fermentative changes generated by the body itself: degradation of proteins, lipids, and carbohydrates, accompanied by the release of gases such as hydrogen sulfide. *Putrefaction*, decomposition by microorganisms and invasive saprobes, follows. *Dry decay* takes place after most fluids have evaporated.

The faunas of decomposing corpses consist primarily of insects, but their exact composition varies with those factors that influence the rate and nature of decomposition: climate, season,

and the condition of the body, including whether it is immersed or buried, wrapped or exposed. Typically, immediately after death, as autolysis begins, blow flies, bluebottles, and house flies arrive to lay eggs. As a detectable odor develops, other flies, including greenbottles and flesh flies, arrive. Fat breakdown, with its accompanying release of volatile fatty acids, attracts a range of carrion-feeding beetles. As proteins decompose, cheese skippers move in. Other species have less interest in the corpse than in the corpse-eaters: rove beetles prey on the maggots that develop from the flies' eggs. During dry decay, skin beetles, hide beetles, and clothes moths (which can feed on the keratin in mammalian hair) dominate. In the final stages of decomposition, spider beetles and other scavengers arrive to feed on the excrement and shed exoskeletons of the insects consuming the corpse. This succession varies tremendously with climate and geography, but within any particular region it is sufficiently predictable that it is admissible in court as evidence of the time since death.

57.4 RECAP

Disturbances are abiotic events that change the probability of persistence of one or more species in an ecological community. Ecological succession—a predictable pattern of change in community composition—typically follows a disturbance.

- How do primary succession and secondary succession differ? **See pp. 1214–1215 and Figures 57.11 and 57.12**
- Describe some ways in which early colonists facilitate or inhibit colonization by the species that follow them in a pattern of succession. **See pp. 1215–1216**

Now that we have seen how communities change in composition over time we will look at how certain communities (such as climax communities) can persist over time and withstand disturbance with little change. In this context, we return to productivity as an important arbiter of community stability.

57.5 How Does Species Richness Influence Community Stability?

Up to a point, higher productivity favors higher species richness, as we saw in Section 57.1. Does species richness in turn influence productivity? And do both of those properties influence community stability? Species richness might enhance productivity because no two species in a community have the same relationship with the environment, so a mixture of more species might result in a more complete use of the available resources. Moreover, if environmental conditions should change, a species-rich community is more likely to contain some species that can persist under the new conditions. Thus a species-rich community should be more *stable*—that is, it should change less over time in either productivity or species composition—than a species-poor community.

Species-rich communities use resources more efficiently

To test the hypothesis that species-rich communities are more stable than species-poor communities, David Tilman and his colleagues at the University of Minnesota cleared several outdoor plots, in which they planted grasses in mixtures ranging from a few to 25 species. At the end of each growing season, they measured total plant cover (a measure of grass biomass, and thus of net primary production) and the population densities of all the grasses in each plot. Over a period of 11 years, which included a serious drought, the plots with more species were more productive, and their productivity was less variable from year to year. These findings were consistent with the hypothesis that species richness promotes productivity and stability (**Figure 57.14A**). Moreover, in the plots with greater species richness, soil nitrogen was used more efficiently (**Figure 57.14B**). However, the population densities of *individual* species in the plots were not stable over the years (regardless of a plot's species richness) because different species performed better during drought years and wet years.

(A) Productivity increases with species richness

(B)

57.14 Species Richness Enhances Community Productivity A total of 120 grassland plots, containing from 2 to 22 grass species, were cultivated for 11 years. (A) The plots with greater species richness showed greater stability (with total plant cover being the measure of stability). (B) The plots with greater species richness utilized soil nitrogen more efficiently, as shown by the smaller amount of nitrogen remaining in the soil.

Researchers continue to debate whether species diversity is responsible for maintaining stability or is simply correlated with stability. This question is important because many of the alterations humans have made in the structure of natural communities have reduced their species richness, and many of these human-altered communities—notably, agricultural communities—are notoriously unstable.

Diversity, productivity, and stability differ between natural and managed communities

Although ecologists have been debating the relationships between community diversity, productivity, and stability for only a few decades, humans have been experimenting with those relationships, albeit inadvertently, for millennia—since plants were domesticated and agriculture was invented. Since the dawn of agriculture, crops have been susceptible to insect **outbreaks**: massive (often sudden) increases in the population sizes of species that destroy or damage crops.

The practice of growing crops as **monocultures**—plantings of only a single species—is one reason why modern agricultural ecosystems are particularly unstable. Most farmers have little tolerance for the presence of any potential competitors for their crops and actively eliminate weeds (and the herbivore species that live with them) from their fields. Thus a typical agroecosystem has very low species diversity. So the answer to the question of whether diversity causes or is merely correlated with stability may be sought in modern farming practices. The predisposition for agroecosystems to play host to outbreaks may well result from human-induced alterations in patterns of community structure.

For the last 20 years, ecologists have been using traditional subsistence agroecosystems as experimental models for testing

the relationships between diversity and stability. Throughout the world, many farmers with small land holdings grow multiple crops on the same plot. In Costa Rica, for example, corn is often grown together with sweet potato. Corn–sweet potato dicultures contain fewer sweet potato pests and many more parasitoid wasps than corn monocultures do. Corn pollen provides nutrition for the wasps, and the tall corn plants act as a structural barrier, shade plant, and source of disruptive chemical signals that interfere with the ability of the sweet potato pests to find their host plants.

In recent years, such applications of community ecology have been paying dividends. Although monoculture is overwhelmingly the dominant agricultural practice, polycultures are under development for agricultural production systems as varied as carp and shrimp farming, vermicomposting (raising worms for compost), and biofuel feedstock production.

57.5 RECAP

Communities with higher species diversity tend to be more productive and more stable than less diverse communities because they use resources more efficiently. Modern agricultural monocultures are notoriously unstable.

- What relationships have ecologists observed between species diversity, community productivity, and community stability? [See p. 1217 and Figure 57.14](#)
- Describe some agricultural practices that might result in more stable ecological communities. [See p. 1218](#)

CHAPTER SUMMARY

57.1 What Are Ecological Communities?

- An ecological **community** is a group of species that coexist and interact within a defined area. The number of species living in a community is its **species richness**.
- **Gross primary productivity (GPP)** is the rate at which the **primary producers** in a community turn solar energy into chemical energy via photosynthesis. **Net primary production (NPP)** represents the energy incorporated into primary producer **biomass** that is available for consumption by heterotrophs. [Review Figure 57.1, WEB ACTIVITY 57.1](#)
- The organisms in a community can be divided into **trophic levels** based on the source of their energy. **Primary producers** get their energy from sunlight; **primary consumers** get their energy by eating primary producers; **secondary consumers** get their energy by eating primary consumers; and so on. [Review Table 57.1, WEB ACTIVITY 57.2](#)
- Organisms that consume the dead bodies of other organisms or their waste products are called detritivores or decomposers. Omnivores are organisms that feed on multiple trophic levels.

- A **food chain** diagrams who eats whom. A **food web** shows how the food chains in a community are interconnected. [Review Figure 57.2](#)
- **Ecological efficiency** is the overall transfer of energy from one trophic level to the next. Pyramid diagrams illustrate the proportions of energy or biomass that flow between trophic levels. [Review Figure 57.3](#)
- Species richness tends to increase with productivity up to a point; however, if productivity increases beyond that point, species richness may decline. [Review Figure 57.4](#)

57.2 How Do Interactions among Species Influence Community Structure?

- The interactions of a consumer with other species can result in a **trophic cascade**: a series of indirect effects across successive trophic levels. [Review Figure 57.5](#)
- Organisms that build structures that create habitat for other species are known as **ecosystem engineers**.
- **Keystone species** have an influence on both the species richness and the number of trophic levels in communities out of proportion to their abundance.

57.3 What Patterns of Species Diversity Have Ecologists Observed?

- **Alpha diversity** is a measure of diversity within a single community or habitat, whereas **beta diversity** is a measure of the change in species composition from one community or habitat to another. **Gamma diversity** is the diversity found over a range of communities in a geographic region.
- Species diversity encompasses species evenness as well as species richness. **Review Figure 57.7**
- Diversity indexes are mathematical formulas used to quantify diversity. The **Shannon diversity index** is a measure of alpha diversity that takes species evenness into account. **Sorensen's index** is a measure of beta diversity.
- Latitudinal gradients in diversity, with the greatest diversity at low latitudes, have been observed in many taxa. **Review Figure 57.8**
- According to the theory of **island biogeography**, the equilibrium number of species on an island represents a balance between the rate at which species immigrate to the island from the mainland **species pool** and the rate at which resident species go extinct. **Review Figures 57.9 and 57.10, ANIMATED TUTORIAL 57.1**

57.4 How Do Disturbances Affect Ecological Communities?

- A **disturbance** is an abiotic event that changes the probability of persistence of one or more species in a community.

- **Succession** is a predictable pattern of change in community composition following a disturbance. In directional succession, species come and go in a predictable sequence until a **climax community** persists for an extended time.
- **Primary succession** begins on sites that lack living organisms. **Secondary succession** begins on sites where some organisms have survived a disturbance. **Review Figures 57.11 and 57.12, ANIMATED TUTORIAL 57.2**
- In any pattern of succession, species that have already become established may **facilitate** or **inhibit** colonization by other species.
- In **cyclical succession**, the climax community is maintained by periodic disturbances.
- **Heterotrophic succession** in detritus-based communities does not rely on photosynthesis and therefore differs in a number of ways from other types of succession.

57.5 How Does Species Richness Influence Community Stability?

- Species-rich communities use resources more efficiently, and thus tend to vary less in productivity, than do less diverse communities. **Review Figure 57.14**
- **Monocultures** are subject to pest outbreaks, whereas agroecosystems containing greater species diversity tend to be more stable.

SELF-QUIZ

- An ecological community is
 - a group of species that coexist and interact within a defined area.
 - a group of species that coexist and interact in an area together with the abiotic environment.
 - all the species in an area that belong to a particular trophic level.
 - all the species that are members of a local food web.
 - all of the above
- A trophic level consists of the organisms
 - whose energy has passed through the same number of steps to reach them.
 - that use similar foraging methods to obtain food.
 - that are eaten by a similar set of predators.
 - that eat both plants and other animals.
 - that compete with one another for food.
- Net primary production is
 - the total amount of photosynthesis in a community.
 - the total amount of primary producer biomass available for consumption by heterotrophs.
 - the total amount of biomass produced by all autotrophs and heterotrophs in a community.
 - the total amount of biomass consumed by heterotrophs.
 - gross primary productivity minus secondary productivity.
- Pyramid diagrams of energy and biomass distribution for forests and grasslands differ because
 - forests are more productive than grasslands.
 - forests are less productive than grasslands.
 - large mammals avoid living in forests.
 - trees store much of their energy in difficult-to-digest wood, whereas grassland plants produce few difficult-to-digest tissues.
 - grasses grow faster than trees.
- Keystone species
 - influence the communities in which they live more than expected on the basis of their abundance.
 - may influence the species richness of communities.
 - may influence the number of trophic levels in communities.
 - are not necessarily predators.
 - all of the above
- Species diversity
 - increases with latitude from the equator to the temperate zone.
 - decreases with latitude from the equator to the temperate zone.
 - shows no consistent pattern from the equator to the temperate zone.
 - increases with latitude from the equator to the temperate zone for terrestrial organisms and decreases with latitude from the equator to the temperate zone for aquatic organisms.
 - increases with latitude from the equator to the temperate zone for animals and decreases with latitude from the equator to the temperate zone for plants.

7. The theory of island biogeography
 - a. predicts that the equilibrium number of species on an island is a balance between the rate of immigration of new species and the rate of extinction of resident species.
 - b. predicts that the rate of immigration of new species will decline with island distance from the mainland species pool.
 - c. predicts that the rate of extinction of resident species will decrease as island size increases.
 - d. applies to isolated habitat patches as well as to oceanic islands
 - e. all of the above
8. Ecological succession is
 - a. the change in species over time.
 - b. the change in community composition after a disturbance.
 - c. the change in a forest as the trees grow larger.
 - d. the process by which a species becomes abundant.
 - e. the buildup of soil nutrients.
9. Primary succession begins
 - a. soon after a disturbance ends.
 - b. at varying times after a disturbance ends.
 - c. at sites where some organisms have survived a disturbance.
 - d. at sites where no organisms have survived a disturbance.
 - e. at sites where only primary producers have survived a disturbance.
10. Early stages of succession are characterized by
 - a. species that are good dispersers.
 - b. species with high intrinsic rates of reproduction.
 - c. simple food webs.
 - d. nutrients that are available primarily in abiotic sources.
 - e. all of the above

FOR DISCUSSION

1. Marek Sammul, Lauri Oksanen, and M. Magi investigated the effect of productivity on species richness by conducting an experiment in 16 different plant communities in western Estonia and northern Norway. They removed one perennial species, the goldenrod *Solidago virgaurea*, from these communities and found that its competitors, particularly the grass species *Anthoxanthum odoratum*, increased in biomass, most noticeably in communities with high productivity (where living plant biomass was greater than 200 g/m²). In less productive communities, such increases could not be detected. How might interspecific competition lead to a decrease in species richness at high levels of productivity? What other hypotheses might explain this puzzling relationship? How would you test them?
2. The increased productivity and stability of species-rich communities could be explained by ecological differences among the species that allow the community as a whole to use resources more efficiently, or by the fact that the more species in a community, the greater the chance that it will contain an unusually productive species. How could you distinguish between these competing hypotheses?
3. If species-rich communities are more productive than species-poor communities, how can modern agriculture, which is based almost entirely on monocultures, be so productive?
4. Figures 57.11 and 57.12 illustrated succession with two examples from forests. How might ecological succession proceed in grasslands? In deserts? In the rocky intertidal zone?

ADDITIONAL INVESTIGATION

The species diversity of aphids (small sucking insects), parasitoid wasps, and kelps decreases, rather than increases, from

the temperate zone to the equator. Can you propose any explanations to account for these unusual patterns?

WORKING WITH DATA (GO TO yourBioPortal.com)

Experimental Island Defaunation This exercise presents the data from Simberloff and Wilson's experiments in the Florida Keys (see Figure 57.10), which were performed in the late 1960s and presented in support of island biogeography theory.

You will be asked to analyze different aspects of the experiment and to draw conclusions as to how (and perhaps whether) the data offer significant support for this theory.

Ecologists swing in the canopy to measure carbon's fate

Photosynthesis by terrestrial plants transforms (*fixes*) the carbon atoms in atmospheric carbon dioxide into the carbohydrate sugars that fuel the fungal and animal worlds. Concentrations of CO₂ in the atmosphere have been rising steadily over the last century, largely as a result of human activities, and some scientists have hypothesized that we can expect rates of photosynthesis—and thus CO₂ fixation and carbon storage in ecosystems—to increase. But ecologists are discovering that this “silver lining” scenario is probably not going to be the case.

Forest studies are important for determining the responses of vegetation to atmospheric carbon enrichment. Most photosynthesis in any forest takes place high up in tree canopies where sunlight is most intense. Until recently, collecting data from forest canopies required

climbing or using balloons. Then, in 1992, Alan Smith at the Smithsonian Tropical Research Institute in Panama realized that he could use a construction crane to gain access to the canopy. He recognized that by swinging the crane's boom in a circle, shuttling the gondola along its length, and lowering the cage to different heights, researchers could reach and measure biological processes over a large volume of the forest canopy. Smith's idea caught on quickly, and today ecologists on four continents use cranes to study forest canopies.

When they monitored growth, reproduction, and carbon storage in large trees, Swiss ecologists found that, as expected, canopy trees increased their growth rates in a carbon-enriched atmosphere; but unlike young, fast-growing saplings, they did not store large amounts of carbon in their trunks and branches. Instead, they trans-

ported more carbon first to the soil, and then to the atmosphere (via their roots). The leaf litter they produced was richer in starch and sugar, but poorer in lignin; the litter decomposed faster as soil microbes rapidly respired the carbon back to the atmosphere. These and other experiments suggest that young forests are likely to respond to greater atmospheric CO₂ concentrations by growing faster. However, mature forests, along with other types of vegetation such as grasslands, shrublands, and tundra, are not likely to store significantly more carbon in response to CO₂ enrichment.

Studying the Canopy A crane 42 meters high allows scientists to study the forest canopy trees of Panama's Smithsonian Tropical Research Institute. One aspect of these studies involves taking measurements that reveal the amount of carbon stored in tropical forest trees.

Enriching the Canopy Researchers from a team of Swiss ecologists install a mechanism of fine tubes that administer controlled amounts of CO₂ to enrich the trees' carbon supply. These experiments simulate what will happen as atmospheric levels of CO₂ increase.

As Chapter 54 described, the global ecosystem is composed of many different types of vegetation (biomes), many of which have few woody plants. To understand how ecosystems function at large scales, scientists must make observations and conduct experiments on many vegetation types. Moreover, because the responses of natural ecosystems to carbon enrichment will depend on many other factors—such as temperature, water, wind, and soil fertility—ecologists must study the interactions among these factors to understand how they influence ecosystem processes.

IN THIS CHAPTER we introduce the compartments of the physical environment through which energy flows and materials cycle. We will trace these events by following the movements of several chemical elements that are crucial to life. In so doing, we highlight many ways in which human activities have altered these cycles. Finally we will consider the many goods and services that ecosystems provide to human society.

CHAPTER OUTLINE

- 58.1** What Are the Compartments of the Global Ecosystem?
- 58.2** How Does Energy Flow through the Global Ecosystem?
- 58.3** How Do Materials Cycle through the Global Ecosystem?
- 58.4** What Services Do Ecosystems Provide?
- 58.5** How Can Ecosystems Be Sustainably Managed?

58.1 What Are the Compartments of the Global Ecosystem?

An **ecosystem** is generally defined as any ecological system with defined boundaries. It includes all of the organisms within those boundaries as well as the physical and chemical factors that influence those organisms. In other words, all ecosystems have both biotic and abiotic components. Ecosystems can occupy a wide range of spatial scales, from the global ecosystem to a watershed, a specific forest, a lake or pond, or even a patch of lichen on a rock. In this chapter we focus on the global ecosystem.

Energy flows and materials cycle through ecosystems

Earth is essentially a closed system with respect to atomic matter, but it is an open system with respect to energy. The sun delivers an essentially constant amount of energy to Earth every day and has done so for billions of years. Energy from the sun, combined with energy from the radioactive decay in Earth's interior, drives the processes that move chemical elements around the planet. The rate at which energy moves through a system is called its *flux*. Elements may accumulate, or *pool*, in some component of an ecosystem; the term *flux* also applies to the movement of elements between pools. Some pools are *sinks*, in which an element is taken out of circulation and locked up for long periods.

Many elements move around the planet in a cyclic fashion (**Figure 58.1**). Nearly all the rocks that make up the continents, for example, have been transformed at least once through a complex cycle of plate tectonic processes (see Figure 25.2). Deep within the Earth, heat, pressure, and melting change the mineral composition of rocks. As the movements of the lithospheric plates push up mountains, the processes of weathering are already wearing them down by breaking rocks into soil and sediment particles (see Section 36.3). Streams carry sediments to the oceans, where they form sedimentary rocks on the seafloor. Eventually, those rocks may be returned to land in another episode of tectonic uplift.

Water is another material that moves cyclically. The water in the oceans today has evaporated, condensed in the atmosphere, precipitated as rain, and returned to the oceans via stream and groundwater flow millions of times. The carbon, nitrogen, oxygen, and sulfur in atmospheric gases have cycled repeatedly through living organisms, which use them to build the proteins that make up their bodies.

58.1 Compartments of the Global Ecosystem The four compartments—atmosphere, oceans, land, and fresh waters—are connected by the flux of materials (arrows). The atmosphere exchanges some components rapidly; exchange of materials within the other compartments (between rocks and soils, for example) is generally much slower.

Earth is a planet with many unusual features: lithospheric plates that move continuously, a moderate surface temperature, a large quantity of liquid water on its surface, and a tremendous diversity of living organisms, to name just a few. The plate tectonic processes that shape Earth's surface also release gases (including carbon dioxide) into the atmosphere through volcanic eruptions. Those atmospheric gases help to moderate planetary temperatures, and those moderate temperatures, in turn, keep water in a liquid state. And living organisms, by virtue of their activities, have an enormous influence on the chemical composition of the atmosphere, the water, and the land.

All organisms depend on inputs of energy (in the form of sunlight or high-energy molecules), liquid water, and nutrients for their metabolism and growth. As described in Section 57.1, energy flows through ecological communities from producers to consumers. At each trophic level, much of this energy is used to power metabolism; that energy is dissipated as heat and lost from the ecosystem (see Figure 57.1). Chemical elements, on the other hand, are not altered when they are transferred among organisms. The availability of the chemical elements of which living organisms are composed is strongly influenced by how organisms get them, how long they retain them, and what they do with them while they have them.

To understand the movements of energy and materials on Earth, the physical environment can be divided into four interacting compartments: the atmosphere, the oceans, fresh waters, and land. These four compartments, and the types of organisms living in them, are very different. Thus the quantities of different elements in each compartment, how long they remain in each compartment (i.e. their *residence time*), and the rates at which they enter and leave the compartments differ strikingly. After describing the four compartments, we will discuss how energy flows through them and elements cycle among them.

The atmosphere regulates temperatures close to Earth's surface

The outermost compartment of the global ecosystem, the *atmosphere*, is a thin layer of gases surrounding Earth. The atmosphere is 78.08% nitrogen gas (N_2), 20.95% oxygen gas (O_2), 1% water vapor, 0.93% argon, and 0.03% carbon dioxide (CO_2). It also contains traces of hydrogen gas, neon, helium, krypton, xenon, ozone, and methane. The atmosphere contains Earth's biggest pool of N_2 as well as a large proportion of its O_2 . Although CO_2 constitutes a very small fraction of the atmosphere, atmospheric CO_2 is the source of the carbon used by terrestrial photosynthetic organisms, and atmospheric CO_2 that dissolves in ocean water is the source of the carbon used by marine primary producers.

About 80% of the mass of the atmosphere lies in its lowest layer, the **troposphere**. This layer extends upward from Earth's surface about 17 km in the tropics and subtropics, but only about 10 km at high latitudes. Most global air circulation takes place within the troposphere, and virtually all of the atmospheric water vapor is found there (Figure 58.2).

58.2 The Two Layers of Earth's Atmosphere The troposphere and the stratosphere differ in their circulation patterns, the amount of water vapor they contain, and the amount of ultraviolet radiation they receive.

The **stratosphere**, which extends from the top of the troposphere up to about 50 kilometers above Earth's surface, contains very little water vapor. Most materials enter the stratosphere from the region of the troposphere that encircles the equator, where air heated by the sun rises to high altitudes (see Section 54.2).

The stratosphere contains a layer of ozone (O_3) that absorbs most of the biologically damaging ultraviolet radiation that enters the atmosphere. Over the last several decades, this **ozone layer** has been seriously damaged by human activities. The widespread release of chlorinated fluorocarbons (CFCs), such as the refrigerant freon, caused chemical reactions in the stratosphere that destroyed ozone molecules. This depletion of stratospheric ozone is a source of great concern, as increases in ultraviolet radiation at Earth's surface are associated with increased rates of skin cancer, cataract formation, and crop damage. In 1989, a group of nations signed a global treaty in which they agreed to phase out production of CFCs, so there is hope that the stratospheric ozone layer will one day be restored.

The atmosphere regulates temperatures at and close to Earth's surface by trapping heat. If Earth had no atmosphere, its average surface temperature would be about -18°C , rather than its actual $+17^\circ\text{C}$. Carbon dioxide, methane, water vapor,

TABLE 58.1

Global Warming Potentials of Three Abundant Greenhouse Gases

	ATMOSPHERIC LIFETIME ^a	GWP ^b
Carbon dioxide (CO_2)	50–200	1
Methane (CH_4)	12	21
Nitrous oxide (N_2O)	114	289

^a Atmospheric lifetime is the number of years these molecules typically remain in the atmosphere before breaking up.

^b GWP (global warming potential) is the ability of a given amount of gas relative to CO_2 (GWP = 1) to trap heat and warm the atmosphere over a specific time period (in this case, 100 years).

and certain other gases in the atmosphere are known as **greenhouse gases** because they are transparent to sunlight, but trap heat radiating from Earth's surface back toward space (**Figure 58.3**) The three major greenhouse gases and their potential effects on atmospheric warming are given in **Table 58.1**. Ozone, when it is present in the troposphere rather than the stratosphere, also acts as a greenhouse gas. As we'll see later in this chapter, human activities are increasing the concentrations of greenhouse gases in the atmosphere, and those increases are making the planet warmer.

The oceans receive materials from the other compartments

Over time scales of hundreds to thousands of years, most materials that cycle through the four compartments of the global ecosystem end up in the oceans. The oceans are enormous, but they exchange materials with the atmosphere only at their surface, so they respond very slowly to inputs from that compartment. They receive materials from land primarily in runoff from rivers.

Except on continental shelves—the shallow ocean waters surrounding large land masses—ocean waters mix slowly. Most materials that enter the oceans from other compartments gradually sink to the seafloor, where they may remain for millions of years until the seafloor sediments are uplifted above sea level by plate tectonic processes. Therefore, concentrations of mineral nutrients are very low in most ocean waters. Some nutrients are brought back to the surface near the coasts of continents, where offshore winds pushing surface waters away from shore cause cold bottom water to rise to the surface. The water in these

58.3 Radiant Energy Warms the Planet Solar energy (yellow arrows) drives the global climate system described in Chapter 54. Much of this energy (in the form of heat) along with the energy generated by Earth's biogeochemical processes (orange arrows) is prevented from radiating back into space by the atmospheric gases. The width of the arrows is roughly proportional to the size of energy flux.

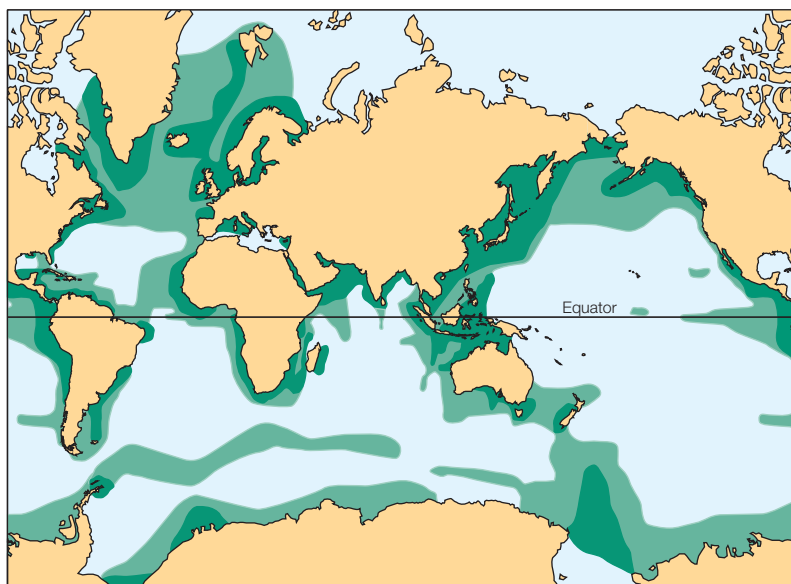

upwelling zones is nutrient-rich because when organisms die their bodies sink to the seafloor and return the materials they contain to the bottom sediments. Upwelling zones support high rates of production by phytoplankton, which in turn support dense consumer populations (**Figure 58.4**). Most of the world's great fisheries are concentrated in upwelling zones. The up-

welling zone off the coast of Peru is, for example, the source of much of the world's supply of anchovies. In turn, this rich fish population supports vast seabird communities, which in turn produce enormous quantities of guano, or droppings, that has provided Peru with an important raw material to support a major fertilizer industry.

Water moves rapidly through lakes and streams

The freshwater compartment of the global ecosystem consists of streams, lakes, and **groundwater** (water occupying pore spaces in rock, sand, and soil). Only a small fraction of Earth's water resides in lakes and streams at any given time, but water moves rapidly through this compartment, so most of Earth's water spends some time there. Some mineral nutrients enter fresh waters in rainfall, but most are released by the weathering of rocks. They are carried into streams by surface runoff or by movement of groundwater.

After entering streams, mineral nutrients are usually carried rapidly to lakes or to the oceans. In lakes, they are taken up by organisms and incorporated into their bodies. Those organisms eventually die and sink to the lake bottom, taking their nutrients with them. Microbial decomposition of their tissues consumes most or all of the oxygen in the bottom water. The surface waters of lakes thus quickly become depleted of nutrients, while deeper waters become depleted of oxygen. This process is countered, however, by verti-

Primary production (mg of carbon per m² per day)

<150	150–250	>250
------	---------	------

58.4 Upwelling Zones Are Highly Productive Biological productivity is greatest near continents where surface waters, driven by prevailing winds, move offshore and are replaced by cool, nutrient-rich water upwelling from below.

58.5 The Turnover Cycle in a Temperate Lake Regular turnovers in spring and fall allow nutrients and oxygen to become evenly distributed in the water column of a lake. The vertical temperature profiles shown here are typical of temperate-zone lakes that freeze in winter.

cal movements of water called **turnover**, which bring nutrients to the surface and oxygen to deeper water.

Wind is an important agent of turnover in shallow lakes, but in deeper lakes it mixes only surface waters. Deep lakes in temperate climates have an annual turnover cycle that depends on certain unique physical properties of water (**Figure 58.5**). Water is densest at 4°C, a few degrees above its freezing point; above and below that temperature, it expands. Thus, in winter, the coldest liquid water in a lake floats at its surface, often covered by a layer of ice. The waters below remain at 4°C. In spring, the sun melts the ice and warms the surface water to 4°C. At this point, water density is uniform throughout the lake, and even modest winds readily mix the entire water column.

As spring and summer progress, the surface water becomes warmer, and the depth of the warm layer gradually increases. However, there is still a well-defined region, called the *thermocline*, where the temperature changes abruptly. Only if the lake is shallow enough to warm right to the bottom does the temperature of the deepest water rise above 4°C. Another turnover occurs in fall as the process reverses itself. The surface of the

lake cools until it is denser than the warmer water below it, at which point it sinks and is replaced by warmer water from below, with wind again mixing the entire water column.

Land covers about a quarter of Earth's surface

About one-fourth of Earth's surface, most of it in the Northern Hemisphere, is currently land above sea level. This *terrestrial* compartment of the physical environment is connected to the atmospheric compartment by organisms that take chemical elements from the air and ultimately release them back into the air. Chemical elements in rocks are released by weathering and carried in solution into groundwater, which transports them ultimately into the oceans, where they are inaccessible to most terrestrial organisms until an episode of tectonic uplift raises marine sediments above sea level and a new cycle of weathering begins.

Even though the global supply of chemical elements in the terrestrial compartment is constant, regional and local variations in the supply of particular elements influence ecosystem processes on land because elements move slowly there and usually over only short distances. The type of soil that exists in an area and the nutrients it contains depend on the underlying rock from which it forms, as well as on climate, topography, the local biota, and the length of time that soil-forming processes have been acting (see Section 36.3).

58.1 RECAP

Earth is a closed system with respect to atomic matter, but an open system with respect to energy. Earth's physical environment can be divided into four compartments—atmosphere, oceans, fresh waters, and land—through which energy flows and elements cycle.

- How does the atmosphere keep temperatures at and close to Earth's surface warmer than they would be in its absence? **See pp. 1223–1224 and Figure 58.3**
- Describe the process of turnover in a temperate-zone lake in fall. **See p. 1226 and Figure 58.5**

Elements cycle through the global ecosystem, but energy flows through it unidirectionally. In the next section we take a brief look at energy flow through ecosystems.

58.2 How Does Energy Flow through the Global Ecosystem?

Solar energy drives nearly all ecosystem processes on Earth. In this section we will examine how the geographic distribution of incoming solar radiation influences the amount of energy assimilated by primary producers, and how human activities are modifying energy flow through the global ecosystem.

The geographic distribution of energy flow is uneven

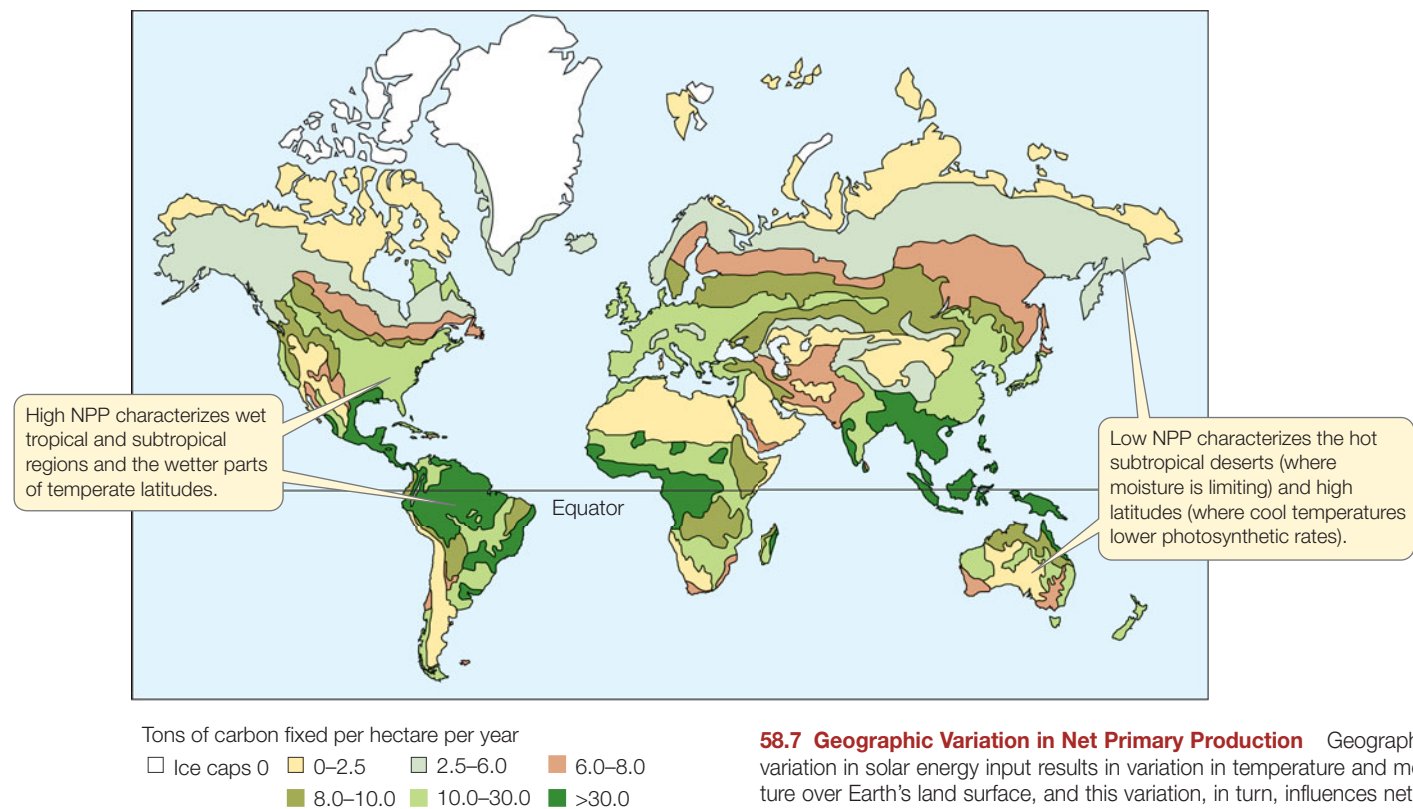

Nearly all energy utilized by organisms comes (or once came) from the sun. The only exceptions are found in those few ecosystems in which solar energy is not the main energy source (such as some caves and deep-sea hydrothermal vent ecosystems). Even the fossil fuels—coal, oil, and natural gas—on which the economy of modern human civilization is based are reserves of captured solar energy locked in the remains of organisms that lived millions of years ago.

As described in Section 57.1, solar energy enters ecosystems by way of plants and other photosynthetic organisms. These primary producers use some of the energy they assimilate for their own metabolism; the rest—net primary production—is stored in their bodies or used for their growth and reproduction (see Figure 57.1). Because only the energy of net primary production is potentially available to other organisms that consume the producers, we use net primary production as a rough measure of energy flow through ecosystems (**Figure 58.6**).

The geographic distribution of net primary production reflects geographic variation in incoming solar radiation, described in Section 53.2, and the climate patterns that result from it. The distribution of land masses, temperatures, and moisture on Earth makes some ecosystems more productive than others

58.6 Primary Production by Ecosystem Type The contributions of the different ecosystem types to primary productivity can be measured by (A) their geographic extent; (B) their net primary production; and (C) their percentage of Earth's total primary production.

58.7 Geographic Variation in Net Primary Production Geographic variation in solar energy input results in variation in temperature and moisture over Earth's land surface, and this variation, in turn, influences net primary production in terrestrial ecosystems.

(**Figure 58.7**). Close to the equator at sea level, temperatures are high throughout the year and the water supply is adequate for plant growth much of the time. In these climates, productive forests thrive. In lower- and mid-latitude deserts, where plant growth is limited by lack of moisture, primary production is low. At still higher latitudes, even though moisture is generally available, primary production is low because it is cold much of the year. Production in aquatic ecosystems is limited by light, which decreases rapidly with depth (see Figure 54.14); by nutrients, which sink and must be replaced by upwelling (see Figure 58.4); and by temperature, which decreases with depth, except in areas on the seafloor near hydrothermal vents.

Human activities modify the flow of energy

Human activities modify energy flows through the compartments of the global ecosystem. The effects of human activities on energy flow have accelerated markedly in the last century, and particularly in the last five decades. Some human activities decrease net primary production, as when forests are cut down and replaced by cities; some increase it, as when prairies are converted to extensive fields of corn and soybeans.

Satellite and climate data indicate that humans consume about 24% of Earth's average annual net primary production. Over half of this appropriation results from direct harvest (cropland and rangeland now occupy over one-third of Earth's ice-free surface); another 40% results from productivity changes brought about by alterations in land use; and 7% results from

fires caused by humans. The percentage varies strikingly among regions; urban areas consume as much as 300 times the net primary production they generate, but people in sparsely inhabited parts of the Amazon Basin appropriate vanishingly small amounts of the net primary production there.

58.2 RECAP

Nearly all energy utilized by living organisms comes from the sun. Energy flow through ecosystems, as measured by net primary production, varies with geographic location and climate.

- How does the distribution of land masses, temperature, and moisture influence the geographic distribution of net primary production? **See pp. 1227–1228 and Figure 58.7**
- What percentage of Earth's average annual net primary production is appropriated by humans, and how does that percentage vary regionally? **See p. 1228**

As we learned in Chapters 3 and 10, most of the biological energy primary producers transform from sunlight is stored in carbon-containing compounds. In the next section we will consider how carbon, as well as other chemical elements required by living organisms, cycle through the four compartments of Earth's physical environment.

58.3 How Do Materials Cycle through the Global Ecosystem?

The chemical elements that organisms need in large quantities—carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur—cycle through the abiotic and biotic components of ecosystems. The pattern of movement of a chemical element through living organisms and the four compartments of the physical environment is called its **biogeochemical cycle**. Each element has a distinctive biogeochemical cycle whose properties depend on the physical and chemical nature of the element and the ways in which it is used by organisms.

Before we describe the biogeochemical cycles of individual elements, however, we must discuss the influences of water and fire on the rates at which elements cycle through ecosystems.

Water transfers materials from one compartment to another

The cycling of water through the four compartments of the physical environment is known as the **hydrologic cycle**. Water is an extraordinary molecule by Earth's standard in that it can be found in all three states of matter—gas, liquid, and solid—and can change state fairly readily. The sun powers the hydrologic cycle by causing evaporation from the vast surfaces of the oceans. The hydrologic cycle operates because more water is evaporated from the ocean surface than is returned to them as

precipitation. Water also evaporates from soils, from lakes and rivers, and from the leaves of plants (by transpiration), but the total amount evaporated from those surfaces is less than the amount that falls on them as precipitation. The excess terrestrial precipitation eventually returns to the oceans via streams, coastal runoff, and groundwater flows (**Figure 58.8**). Earth's 16 largest rivers account for more than one-third of total runoff from the land. More than half of this total comes from the four largest rivers—the Amazon in South America, the Nile in Africa, the Mississippi in North America, and the Yangtze in Asia.

Despite their relatively small volume, rivers play a disproportionate role in the hydrologic cycle because the average residence time of a water molecule in rivers is only a few years. By comparison, the average residence time of a water molecule in lakes ranges from a few years to centuries. The larger the lake, the longer the residence time; the residence time for Lake Michigan, for example, is about 600 years, and the residence time of the top portion of Lake Superior is 1,500 to 2,000 years (and the brackish water at the bottom never cycles). In the ocean, the average residence time of a water molecule is about 3,000 years. Other accumulations of water include glaciers (with residence times of 20–100 years), seasonal snow cover (a few months), and soil moisture (a month or two). The average residence time of water in organisms is particularly brief—on average, just under a week.

Although large amounts of groundwater are present in underground pools called **aquifers**, this water has a long residence time underground and plays only a small role in the hydrologic

58.8 The Global Hydrologic Cycle The numbers show the estimated relative amounts of water (expressed as units of 10^{18} grams) held in or exchanged annually by ecosystem compartments. The widths of the arrows are proportional to the sizes of the fluxes.

yourBioPortal.com

GO TO Animated Tutorial 58.1 • The Global Hydrologic Cycle

cycle. In some places, however, groundwater is being seriously depleted because humans are using it more rapidly than it can be replaced, primarily by pumping it for irrigation. Much of the groundwater being used today in the Northern Hemisphere was deposited during the most recent ice age, when regional precipitation was much greater than it is now. Using this groundwater for irrigation and other purposes has increased flows of water to the oceans and has contributed to the sea level rise of the past century.

The effects of groundwater depletion are already being felt. On the North China Plain, for example, depletion of shallow aquifers is forcing people to sink wells more than 1,000 meters deep to reach water. Worldwide, more than 1 billion people have no access to safe drinking water. If current water consumption patterns continue, by 2025 at least 3.5 billion people (48% of the current world population) will live in areas with inadequate water supplies. However, per capita water consumption in the United States and Europe is dropping as a result of increasing use of water-efficient home appliances and the increasing cost of water, as well as new regulations that restrict water use. If such programs are implemented vigorously, global water use in 2025 could be lower than it is today, despite continued population growth.

Fire is a major mover of elements

Every year, 200–400 million hectares of savannas, 5–15 million hectares of boreal forests, and smaller expanses of other biomes burn. Lightning ignites some fires, but humans start most fires to manage vegetation (as when they cut down and burn forests to clear land for growing crops). Fires consume the energy stored in, and release chemical elements from, the vegetation

they burn. Some nutrients, such as nitrogen, are easily vaporized by fire. They are discharged to the atmosphere in smoke or carried into groundwater by rain falling on burned ground.

Fires also release large amounts of carbon into the atmosphere. The global annual flux of carbon to the atmosphere from savanna and forest fires is estimated at 1.7 to 4.1 petagrams (1 pg = 10^{15} g or 10^{12} kg). Biomass burning (which includes combustion of wood and alcohol, wildfires, and land clearing, but not the burning of fossil fuels) is responsible for about 40% of Earth's annual flux of CO_2 into the atmosphere and contributes to the production of other greenhouse gases. Large-scale wildfires in the western and southeastern U.S. can release as much CO_2 into the atmosphere as motor vehicles in those regions release over an entire year.

Although biogeochemical cycles interact with one another, it is convenient to discuss the major cycles individually. Our discussion will focus on those elements whose cycles are best characterized and have the greatest effect on living organisms.

The carbon cycle has been altered by human activities

As described in Part One of this book, all the important macromolecules that compose living organisms contain carbon, and much of the energy that organisms need to fuel their metabolic activities comes from carbon-containing (organic) compounds. Carbon in the atmosphere, in the form of CO_2 , is incorporated into organic molecules by photosynthesis in the cells of autotrophs. All heterotrophic organisms get their carbon by consuming autotrophs or other heterotrophs, their remains, or their waste products. Most of the carbon stored in the terrestrial compartment over the short term is stored as organic matter in soils. Biological processes move carbon between the atmospheric and terrestrial compartments, removing it from the atmosphere during photosynthesis and returning it to the atmosphere through metabolism (Figure 58.9).

58.9 The Global Carbon Cycle The numbers show the quantities of carbon (expressed as petagrams) held in or exchanged annually by ecosystem compartments. The widths of the arrows are proportional to the sizes of the fluxes.

yourBioPortal.com

GO TO Animated Tutorial 58.2 • The Global Carbon Cycle

The amount of carbon in the atmosphere in the form of CO_2 , and the amount stored in the biosphere in living and dead organisms, are dwarfed by the amount of carbon stored in terrestrial soils and rocks, in marine sediments, and in dissolved form in ocean waters. Carbon dioxide moves into ocean waters from the atmosphere primarily by simple diffusion at the ocean surface; it is stored in seawater in the form of carbonate (CO_3^{2-}) or bicarbonate (HCO_3^-).

—yourBioPortal.com—

GO TO Animated Tutorial 58.3 • The Ocean Conveyor Belt

Today's oceans absorb 20–25 million tons of CO_2 every day—more than at any time during the past 20 million years. As a result, water near the ocean surface is becoming more acidic. An increase in the acidity of ocean surface waters could have negative effects on many marine organisms, particularly corals. The combination of decreasing pH and increasing water temperature kills their symbiotic algae, “bleaching” the corals and killing them as well (see Figure 27.8A). Because so many other reef species depend on corals and the structure they provide, the entire reef community collapses.

At times in the remote past, great quantities of carbon were removed from the global carbon cycle when organisms died in large numbers and were buried in sediments lacking oxygen. In such anaerobic environments, detritivores do not reduce organic carbon to CO_2 . Instead, organic molecules accumulate and are eventually transformed into deposits of oil, natural gas, coal, or peat. Humans have discovered and used these deposits, known as **fossil fuels**, at ever-increasing rates during the past 150 years. As a result, CO_2 , one of the final products of the burning of fossil fuels, is being released into the atmosphere faster today than it is dissolving in the oceans or being incorporated into terrestrial biomass. Based on a variety of calculations, atmospheric scientists believe that before the Industrial Revolution, the concentration of atmospheric CO_2 was probably about 265 parts per million. Today, it is 387 parts per million (Figure 58.10), representing a rate of increase more than 10 times faster than at any other time for millions of years.

WHERE HAS ALL THE CARBON GONE? Less than half of the vast amount of CO_2 released into the atmosphere by human activities remains in the atmosphere. Where is the rest? Much of it is dissolved in the oceans. Over decades to centuries, the oceans, which contain 50 times more dissolved inorganic carbon than the atmosphere, determine atmospheric CO_2 concentrations. The rate at which CO_2 moves from the atmosphere to the oceans depends, in part, on photosynthesis by phytoplankton in the surface waters. These organisms remove carbon from the water, thereby increasing its absorption from the atmosphere. In addition, many marine organisms, including clams, oysters, corals, and some algae, combine bicarbonate ions with calcium (Ca^{2+}) to form calcium carbonate, which they use to build shells and other structures. When these organisms die, they eventually sink to the ocean floor.

Photosynthesis by terrestrial vegetation, principally in forests and savannas, typically absorbs roughly the same amount of carbon that is released by metabolism—about half of it by plants and half of it by microbes in the soil that break down organic matter produced by plants. Currently, the photosynthetic consumption of CO_2 exceeds the metabolic production of CO_2 , so Earth's terrestrial vegetation is storing carbon that would otherwise be increasing atmospheric CO_2 concentrations. Yet, as we saw at the opening of this chapter, we cannot count on terrestrial vegetation to store the extra CO_2 that human activities are producing. Furthermore, climate warming—another result of increasing CO_2 concentrations, as we'll see next—increases plant metabolism and is thus likely to increase the flux of CO_2 from vegetation to the atmosphere.

ATMOSPHERIC CO_2 AND GLOBAL WARMING What evidence do we have that the buildup of atmospheric CO_2 stemming from the burning of fossil fuels is raising Earth's temperature? Measurements of gases in air trapped in the Antarctic and Greenland ice caps show that atmospheric CO_2 levels have been higher when Earth has been warmer and lower when it has been cooler (Figure 58.11). For example, atmospheric CO_2 was very low during the most recent glaciation, between 30,000 and 15,000 years ago,

when temperatures were presumably much colder than they are today. In contrast, during a warm interval 5,000 years ago, atmospheric CO_2 may have been slightly higher than it is today.

How global climates and ecosystems will change in response to this rapid warming is a subject of intense investigation. Complex computer models of the global ecosystem indicate that a doubling of the atmospheric CO_2 concentration from today's level would increase

58.10 Atmospheric CO_2 Concentrations Are Increasing

These carbon dioxide concentrations, expressed as parts per million by volume of dry air, were recorded on top of Mauna Loa, Hawaii, far from most sources of human-generated CO_2 emissions.

58.11 Higher Atmospheric CO₂ Concentrations Correlate with Warmer Temperatures

The geological record of variation in atmospheric CO₂ concentrations over the last 500 million years shows that CO₂ levels have been lowest during times of extensive continental glaciation (red bars), and thus presumably lower temperatures.

Global warming is having a profound effect on the distribution and abundance of interacting species. One clear example is an increase in the severity of insect infestations in certain temperate forest communities. Pine trees in these forests are attacked by pine bark beetles, which carry with them a symbiotic fungus that infects the trees and helps the beetles to overcome the trees' defenses (see Figure 56.13). In Colorado, cold winters have historically limited the ability of these beetles to kill many trees. In 2008, however, Colorado experienced an outbreak of mountain pine beetles larger than any previously recorded; more than a million acres of trees were killed. The lack of an extended period of below-zero temperatures in the previous winter had allowed large numbers of overwintering beetles to survive.

Another result of global warming may be an increase in the frequency of outbreaks of human diseases. Winter cold typically kills many pathogens, sometimes eliminating as much as 99% of a pathogen population. If climate warming reduces this population bottleneck, some diseases will spread to more temperate regions. For example, dengue fever and its mosquito vector are now spreading to higher latitudes where they were formerly absent.

The 2007 Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) forecast these and many other negative effects of global warming on humans, warning, "Human beings are exposed to climate change through changing weather patterns (for example, more intense and frequent extreme events) and indirectly through changes in water, air, food quality and quantity, ecosystems, agriculture, and economy. At this early stage the effects are small but are projected to progressively increase in all countries and regions."

Recent perturbations of the nitrogen cycle have had adverse effects on ecosystems

Nitrogen gas makes up 78% of Earth's atmosphere, but most organisms cannot use nitrogen in its gaseous form. Only a few species of microorganisms can convert atmospheric N₂ into forms that are usable by plants, a process called *nitrogen fixation* (see Section 36.4). Nitrogen-fixing bacteria are often found as symbiotic associates in the root nodules of plants such as legumes. Other microorganisms carry out *denitrification*, the principal process that removes nitrogen from the biosphere and returns it to the atmosphere as N₂ (see Figure 36.11). These denitrifying microbes are found in places where oxygen levels are

mean annual temperatures worldwide and would probably cause droughts in the central regions of continents while increasing precipitation in coastal areas. Global warming has already resulted in the shrinking of Arctic sea ice (Figure 58.12). If the polar ice caps continue to melt, sea level will rise (due to both thermal expansion of ocean waters and the addition of glacial meltwater), flooding coastal cities and agricultural lands. Because the rate at which water evaporates from the ocean surface increases with temperature, tropical storms are likely to become more intense. Indeed, during the past two decades, the number of hurricanes generated per year worldwide has not increased, but the number of severe (category 4 and 5) hurricanes has.

58.12 The Ice Caps Are Melting

Global warming is causing major changes in the sizes of the polar ice caps. In 2008, for the first time in recorded history, enough of the Arctic Ocean was ice-free that the North Pole could have been circumnavigated by ship.

58.13 The Global Nitrogen Cycle

Cycle The numbers in parentheses show the quantities of nitrogen (expressed as teragrams) held in or exchanged annually by ecosystem compartments. Arrow widths are proportional to the sizes of the fluxes.

yourBioPortal.com

GO TO Animated Tutorial 58.4 • The Global Nitrogen Cycle

low, such as bogs, swamps, and marine sediments. Collectively, this microbial processing of nitrogen accounts for about 95 percent of all natural nitrogen flux on Earth (Figure 58.13).

All living organisms require nitrogen, and the inability of the vast majority of them to utilize N_2 means that usable nitrogen is often in short supply in ecosystems. Populations of nitrogen-fixing organisms rarely increase in abundance to the extent that nitrogen is no longer limiting because the end products of nitrogen fixation are rapidly lost from ecosystems: ammonia by

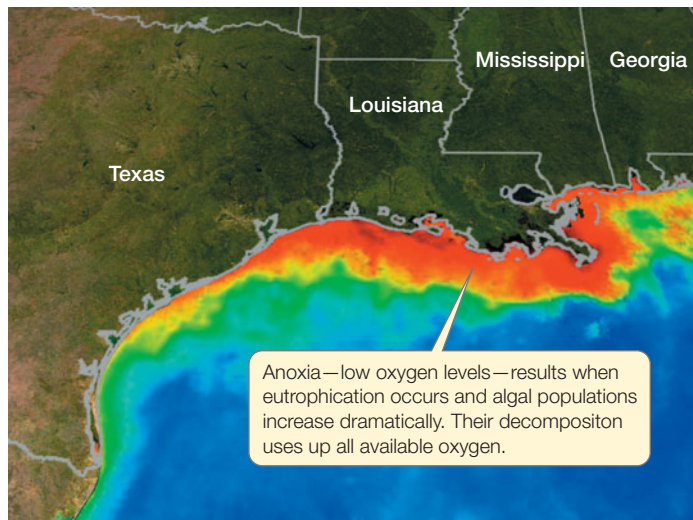

vaporization and denitrification, and the highly water-soluble nitrates by leaching. Furthermore, fixing nitrogen requires large amounts of energy. Thus nitrogen-fixing organisms often lose out in competition with non-fixers when nitrogen becomes more readily available.

The industrial production of inexpensive artificial fertilizers has had some unanticipated effects on the nitrogen cycle. As a result of extensive use of these fertilizers on agricultural crops, coupled with the burning of fossil fuels (which generates nitric oxide), total industrial nitrogen fixation by humans today is about equal to global natural nitrogen fixation. This human-generated nitrogen flux has been increasing over the past half-century and is expected to continue to increase during the coming decades (Figure 58.14).

These large perturbations of the nitrogen cycle have had numerous adverse effects. When more nitrogen is applied to croplands than can be taken up by the crops, the excess nitrogen moves out of the system in surface runoff, or downward into groundwater, and ultimately ends up in rivers, lakes, and oceans. The addition of nutrients to these bodies of water, known as **eutrophication** (“rich food”), can have dramatic effects on aquatic ecosystems. The “dead zone” that has formed

58.14 Human Activities Have Increased Nitrogen Fixation Most of the industrially fixed nitrogen (produced by humans by combining, at high pressure and temperatures, atmospheric nitrogen with hydrogen derived from fossil fuels) is manufactured for use in agricultural fertilizers. Some nitrogen fixation is a by-product of fossil fuel combustion.

near the mouth of the Mississippi River in the Gulf of Mexico is a result of flows of water from agricultural fields in the Upper Midwest carrying high concentrations of nitrogen from fertilizer (**Figure 58.15**). The high nutrient levels that result promote luxuriant algal growth. When the algae die, their decomposition by microbes uses up the oxygen in the water, and the resulting anaerobic conditions kill most other marine organisms. Given that the Gulf of Mexico is a key resource for the seafood industry, providing almost three-fourths of the shrimp and two-thirds of the oysters harvested in the United States, an expansion of the dead zone could have a devastating effect on the economies of the Gulf region, over and above its effects on biodiversity and ecosystem function.

The increase in nitrogen fixation has also increased atmospheric concentrations of the greenhouse gas nitrous oxide (N_2O ; see Table 58.1), resulting in the production of tropospheric O_3 —also a greenhouse gas—and smog. Some of the nitrogen that enters the atmosphere falls back to land in precipitation or as dry particles. This deposition of nitrogen affects the composition of terrestrial vegetation by favoring those species that are best adapted to take advantage of high nutrient levels, which then crowd out other species. Atmospheric deposition of nitrogen has increased dramatically during recent decades due to human activity. Spatial variation in nitrogen deposition rates has allowed ecologists to determine that plant species richness in grasslands declines as the rate of nitrogen deposition increases. Rates of nitrogen deposition are high enough over much of Europe and eastern North America to cause substantial reductions in species richness in grasslands on both continents.

The burning of fossil fuels affects the sulfur cycle

Most of Earth's sulfur supply is locked up in rocks on land and as sulfate salts in deep-sea sediments. Emissions of the gases sulfur dioxide (SO_2) and hydrogen sulfide (H_2S) from volcanoes account for, on average, 10–20% of the total natural nonbiological flux of sulfur to the atmosphere, but they occur only intermittently. Although volcanic eruptions spew great quantities of sulfur over

58.15 A Dead Zone High concentrations of nitrogen and phosphorus in the runoff from agricultural lands in the midwestern United States are carried by the Mississippi River to the Gulf of Mexico. This nutrient enrichment causes excessive algal growth, depleting the oxygen in the water and creating a deoxygenated “dead zone” in which few aquatic organisms can survive.

broad areas, they are rare events. Sulfur in soil is taken up by plants and incorporated into proteins; ultimately, this sulfur is returned to the atmosphere via microbial decomposition. In marine systems, too, microbial decomposition is important in returning sulfur to the atmosphere. In particular, many marine phytoplankton and seaweeds manufacture large quantities of a sulfur-containing compound (DMSP, or dimethylsulfoniopropionate) to maintain their salt and water balance; when broken down, this compound releases dimethyl sulfide (CH_3SCH_3), the principal odorant of rotting seaweed stench. Because the quantities of phytoplankton in the vast oceans are enormous, dimethyl sulfide production accounts for about half of the biotic component of the global sulfur cycle.

Atmospheric sulfur plays an important role in global climate. Even if air is moist, clouds do not form readily unless there are small particles in the atmosphere around which water can condense. Dimethyl sulfide is the major component of such particles. Therefore, increases in atmospheric sulfur concentrations can increase cloud cover and reduce the amount of incoming solar radiation that ultimately reaches Earth's surface.

The burning of fossil fuels alters the sulfur cycle as well as the carbon and nitrogen cycles. The combustion of fossil fuels releases sulfur in the form of SO_2 and nitrogen in the form of nitrogen dioxide (NO_2) into the atmosphere, where they react with water molecules to form sulfuric acid (H_2SO_4) and nitric acid (HNO_3). These acids can travel hundreds of kilometers in the atmosphere before they settle to Earth as dry particles or in precipitation. Rain or snow containing sufficient levels of nitric and sulfuric acids to lower its pH is called **acid precipitation**. Acid precipitation now falls in all major industrialized countries and is particularly widespread in eastern North America and Europe. The normal pH of unpolluted precipitation is about 5.6, but precipitation in New England now averages about pH 4.5 and there have been occasional rainfalls and snowfalls with a pH as low as 3.0. Precipitation with a pH of about 3.5 or lower damages the leaves of plants and reduces rates of photosynthesis. Acidification of lakes in the Adirondack region of New York State has reduced fish species richness by causing the extinction of acid-sensitive species (**Figure 58.16**). Many invertebrates that are primary consumers in aquatic communities are sensitive to pH; in particular, multiple species of mayflies and caddisflies have experienced local population reductions in acidified streams around the world. Even when its effects are not lethal, acidification can have subtle effects on behavior that reduce the viability of aquatic organisms. Diving beetles, for example, lose their ability to regulate their underwater oxygen supply when pH levels drop significantly.

New regulations instituted by the 1990 Clean Air Act have raised the pH of precipitation in much of the eastern United

58.16 Acidification of Lakes Exterminates Fish Species The number of fish species found in lakes in the Adirondack region of New York State is directly correlated with pH. The numbers in the bars indicate the number of lakes in each pH range.

States, primarily by lowering sulfur emissions. There are indications that, once emissions have been reduced, acidified aquatic systems can recover quickly. David Schindler at the University of Alberta studied the effects of acid precipitation by adding enough H_2SO_4 to two small Canadian lakes to reduce their pH from about 6.6 to 5.2. In both lakes, nitrifying bacteria failed to survive under these moderately acidic conditions. As a result, the nitrogen cycle was blocked. When Schindler stopped adding acid to one of the lakes, its pH returned to its original value in about a year, and nitrification resumed. These experiments show that lake ecosystems are very sensitive to acidification but can recover rapidly, presumably because water in lakes is exchanged rapidly.

That said, the larger organisms in such systems may be slower to bounce back. Fourteen rivers in Wales were studied for a quarter-century, to determine the impacts of acid rain reductions. Investigators were disappointed that, even after 25 years, only four insect species—two mayfly species and two caddisfly species—had recolonized the area out of the 29 species expected to come back.

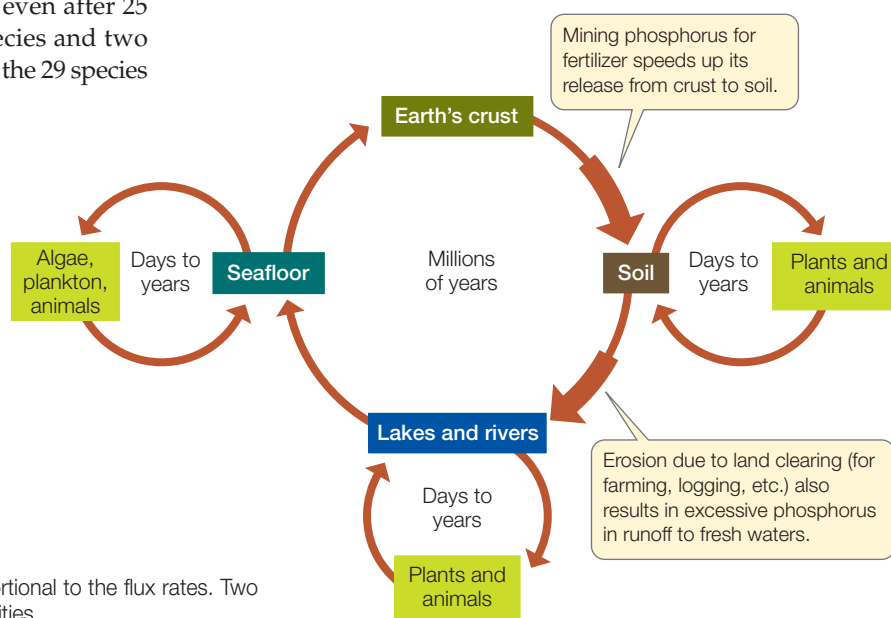

The global phosphorus cycle lacks a significant atmospheric component

Phosphorus accounts for only about 0.1% of Earth's crust, but it is an essential nutrient for all life forms. It is a key component of DNA, RNA, and ATP. Unlike the elemental cycles discussed thus far, the phosphorus cycle lacks a significant gaseous component. Some phosphorus is transported on dust particles, but very little of the phosphorus cycle takes place

in the atmospheric compartment. Most of Earth's phosphorus is present in the form of phosphate salts in rocks and deep-sea sediments. Phosphorus cycling takes millions of years because the processes of sedimentary rock formation, uplift, and weathering all take a long time (Figure 58.17). In contrast, phosphorus often cycles rapidly among organisms, and it is often a limiting factor for their growth, particularly for plants. In addition to nitrogen, fertilizers routinely include phosphorus.

Human activity has radically accelerated some parts of the phosphorus cycle. One consequence of the massive use of artificial fertilizers is that between 10.5 and 15.5 teragrams (1 tg = 10^{12} g or 10^9 kg) of phosphorus accumulate each year, primarily in agricultural soils. When the concentration of phosphorus in soils exceeds the capacity of plants to take it up, the excess moves into streams and lakes. Soil erosion due to the clearing of land for purposes such as agriculture and logging also increases the amount of phosphorus and other nutrients in runoff. Phosphorus is a limiting nutrient in many lakes, so when it enters those lakes through runoff, algae previously limited by relatively low levels of phosphorus respond with phenomenal growth. These algal blooms turn the water green and, depending on the metabolic capabilities of the algae, toxic. When the algae die, their decomposition by microbes consumes all of the oxygen in the lake, and anaerobic organisms dominate the bottom sediments. These anaerobic organisms do not break down carbon compounds all the way to CO_2 , and their metabolic end products, many of which have unpleasant odors, build up.

The capacity of phosphorus-charged runoff to cause extensive eutrophication was graphically illustrated almost 50 years ago. A technological innovation in the formulation of laundry detergents in the early 1960s was the use of sodium tripolyphosphate (STPP) ($\text{Na}_5\text{P}_3\text{O}_{10}$) as a water softener and dirt-breaking agent to enhance cleaning efficiency. Widespread adoption of these new detergents led to massive phosphorus enrichment of lakes and streams and concomitant eutrophication and algal blooms. Water quality declined so much across the United States that phos-

58.17 The Phosphorus Cycle Arrow widths are proportional to the flux rates. Two large increases in phosphorus flux are due to human activities.

phate-based detergents were banned in many states, as well as in Europe. In today's detergents, phosphonates—forms of phosphorus that do not appear to promote algal growth—and aluminum silicates perform the functions STPP used to serve.

Detergents, however, are only one agent contributing to eutrophication. Human waste is rich in phosphorus, as are manure from domesticated animals and industrial waste of various types. Two hundred years ago, Lake Erie, one of the Great Lakes on the border between the United States and Canada, had only moderate rates of photosynthesis and clear, oxygenated water. With increasing industrialization in the early part of the twentieth century, nutrient concentrations in the lake increased greatly, and algae proliferated. At the water filtration plant in Cleveland, Ohio, algae increased from 81 per milliliter in 1929 to 2,423 per milliliter in 1962. Populations of bacteria also increased: the numbers of *Escherichia coli* increased enough that many of the lake's beaches were closed and declared health hazards. Since 1972, the United States and Canada have invested more than U.S. \$9 billion to improve municipal waste treatment facilities and reduce discharges of pollutants into Lake Erie. As a result, the amount of phosphorus added to Lake Erie has decreased more than 80% from its highest level, and phosphorus concentrations in the lake have declined substantially. The deeper waters of Lake Erie are still oxygen-poor during the summer months, but the rate of oxygen depletion is declining.

We could greatly reduce phosphorus pollution by recovering and recycling phosphorus. The phosphorus contained in sewage and animal wastes could supply much of the needs of the detergent and fertilizer industries. More careful application of fertilizers on agricultural lands could reduce the rate of phosphorus accumulation in soils without reducing crop yields. However, reduction of phosphorus concentrations in soils will take many decades after remedial actions are initiated, and eutrophication of lakes and streams may persist even after these actions are taken.

Other biogeochemical cycles are also important

Other elements, in addition to those we have just discussed, are important to the global ecosystem because they are essential nutrients for organisms, even though they are needed only in very small amounts. One such element is *iron* (Fe), an essential micronutrient for almost all organisms. It is a key component of the enzymes involved in chlorophyll synthesis, as well as an essential component of many animal enzymes. Iron confers oxygen-binding ability on hemoglobin in vertebrate blood and the cytochrome P450 monooxygenases, which in most aerobic organisms play a central role in detoxifying environmental poisons, rely upon iron for their catalytic activity.

Iron is readily available on land in rocks and minerals. It moves into coastal waters in streams and into the open ocean in atmospheric dust. Because iron is insoluble in oxygenated water, it rapidly sinks to the ocean floor. Therefore, in most ocean communities, the rate of photosynthesis is limited by iron. In 1996, investigators launched an ecosystem-scale experiment in which surface waters of the equatorial Pacific Ocean were seeded with dissolved iron. The response was a tremendous

phytoplankton bloom, accompanied by massive uptake of nitrate and carbon dioxide, which had apparently been underutilized due to iron limitation.

Three micronutrients that are relatively rare globally—iodine (I), cobalt (Co), and selenium (Se)—are of particular importance to living organisms because they regulate the production and functioning of many metabolic agents, including hormones, vitamins, and enzymes that contain zinc and copper.

- *Iodine* is found on land in mineral deposits and in seawater as an inorganic salt; fresh water is a relatively poor source. Iodine, which is supplied to land primarily by marine algae that release it to the air, is often deficient in continental interiors. It is an essential component of the hormone thyroxine, which governs many metabolic processes, and a deficiency of iodine in humans leads to the medical condition called goiter (see Figure 41.10).
- *Cobalt* is a rare element found in soil and rocks. The bacteria that fix atmospheric nitrogen require coenzymes derived from cobalt. As an essential component of vitamin B₁₂, it is a dietary requirement for almost all animals and is important for the synthesis of proteins.
- *Selenium* is also found in soil and rocks. It is a component of several important mammalian enzymes, such as the antioxidant glutathione peroxidase (which protects tissues from oxidative damage) and several enzymes involved in synthesizing thyroid hormones.

Land plants require all three of these micronutrients in minimal concentrations, but animals, particularly endothermic vertebrates, require them in concentrations that exceed the supply in many environments. Herbivores sometimes obtain these nutrients by drinking water at mineralized springs or by eating enriched earth (see Figure 53.14). Deficiencies of these elements are most common in areas with high rainfall and soils that leach readily.

Biogeochemical cycles interact

The biogeochemical cycles of different elements interact with one another in complex ways, and perturbations to one cycle can have profound effects on other cycles. In recent years, human-induced perturbations have made these interactions glaringly apparent. For example, nitrate released by human activities can have profound effects on the biogeochemical cycles of iron and arsenic. Nitrate is a powerful oxidant, and nitrate pollutants can increase the movement of arsenic in lakes by causing its oxidation. Some urban lakes have arsenic levels in excess of 2,000 parts per million locked in sediments; oxidation releases arsenic into the water column in a form that is carcinogenic and has negative effects on development. Every year, scientists are discovering interactions of which they were previously unaware, and experiments exploring biogeochemical interactions are increasing in number.

Changes in atmospheric CO₂ concentrations have been a particular focus of investigation in recent years because of their potential for interacting with other biogeochemical cycles through photosynthesis. A case in point is a study of whether elevated atmospheric CO₂ concentrations affect rates of nitro-

INVESTIGATING LIFE

58.18 Effects of Atmospheric CO₂ Concentrations on Nitrogen Fixation

Although the original expectation was that CO₂ enrichment would enhance nitrogen fixation, the reverse—decreased fixation—was in fact being observed. In an attempt to explain this result, investigators studied the changes in concentrations of iron and molybdenum, two micronutrient components of enzymes that are essential to nitrogen fixation.

HYPOTHESIS Higher CO₂ levels should enhance nitrogen fixation.

- METHOD**
1. Grow nitrogen-fixing vines (*Galactia elliottii*) in plots under control conditions (normal levels of CO₂) and experimental conditions of artificially heightened levels of atmospheric CO₂.
 2. Measure levels of nitrogen fixation over a period of 7 years.
 3. Determine the concentrations of iron and molybdenum in the leaves of *G. elliottii* at year 7.

RESULTS

CONCLUSION Decreasing rates of nitrogen fixation associated with increased concentrations of atmospheric CO₂ correlate with lower concentrations of essential iron and molybdenum in plant tissues; thus the initial increase in the rate of fixation can result in its eventual depression.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

gen fixation by microorganisms associated with plant roots. A group of ecologists grew a nitrogen-fixing vine called Elliott's milkpea (*Galactia elliottii*) under artificially increased CO₂ concentrations. Higher CO₂ concentrations led to an enhancement

of nitrogen fixation during the first year of the experiment, but surprisingly, the positive effect disappeared by the third year, and elevated CO₂ concentrations actually *reduced* nitrogen fixation below normal levels during the fifth, sixth, and seventh years of the experiment (**Figure 58.18**). The experimenters suspected that depletion of micronutrients such as iron and molybdenum caused the reduction in nitrogen fixation, so they measured concentrations of those elements in the leaves of *G. elliottii*. They found that concentrations of molybdenum were particularly low. Elevated CO₂ can increase the acidity of water in soil by enhancing the rate of carbonic acid formation and, by enhancing photosynthesis, increase the accumulation of soil organic matter; both types of change increase the tendency of molybdenum to adsorb onto soil particles, reducing its availability to nitrogen-fixing bacteria and causing a decrease in nitrogen fixation rates.

58.3 RECAP

The pattern of movement of a chemical element through organisms and the physical environment is its biogeochemical cycle. Human activities have affected many biogeochemical cycles, especially those of water, carbon, nitrogen, sulfur, and phosphorus. Increasing concentrations of carbon dioxide and other greenhouse gases in the atmosphere are implicated in global warming.

- Describe the global hydrologic cycle and explain what drives it. **See pp. 1229–1230 and Figure 58.8**
- How do biological processes move carbon from the atmospheric compartment to the terrestrial compartment and then return it to the atmosphere? **See pp. 1230–1231 and Figure 58.9**
- What are some results of human-induced alterations of the sulfur and nitrogen cycles? **See pp. 1232–1234**
- Name two elements that can cause eutrophication in aquatic ecosystems and describe their effects on those systems. **See pp. 1235–1236**

The biogeochemical cycles of chemical elements are intimately involved in ecosystem function. Just as human alterations of those cycles are having many effects on ecosystems worldwide, the resulting changes in those ecosystems are having profound effects on human lives.

58.4 What Services Do Ecosystems Provide?

Although it seems obvious today that humans depend on natural ecosystems for survival, explicit recognition of the value of those ecosystems is rather recent. Environmental writers introduced the idea of “natural capital” in the 1940s; it was in 1970 that ecosystems were first said to provide people with a variety of “goods and services.” The goods include food, clean water, clean air, fiber, building materials, and fuel; the services include

flood control, soil stabilization, pollination, and climate regulation. Most of these benefits either are irreplaceable, or the technology necessary to replace them is prohibitively expensive. For example, potable fresh water can be provided by desalinating seawater, but only at great cost. The aesthetic, psychological, spiritual, and recreational benefits of ecosystems are less tangible, but no less important, and no more easily replaced.

Humans have increasingly altered Earth's ecosystems to increase their capacity to provide us with goods such as food, fresh water, timber, fiber, and fuel. The benefits have not, however, been equally distributed, and some human populations have actually been harmed by our manipulations of natural ecosystems. Moreover, short-term increases in some ecosystem goods and services have come at the cost of the long-term degradation of others.

The most important driver of change in ecosystems has been changes in land use as natural ecosystems have been converted to other, more intensive uses. Although humans have been altering ecosystems for millennia, the pace and scope of the alterations have increased considerably in recent years. More land was converted to cropland between 1950 and 1980 than in the 150 years between 1700 and 1850. Ecosystem conversions have been particularly rapid in tropical and subtropical biomes. Aquatic ecosystems have suffered losses at an increasing pace as well. Between 1970 and 2000, about 20% of the world's coral reefs were lost, and an additional 20% were degraded. In freshwater ecosystems, so much water is now impounded behind dams that artificial reservoirs hold about six times as much water today as do natural rivers. These freshwater systems are being rapidly depleted: the amount of water withdrawn from rivers—most of it for agriculture—has doubled since 1960. In terms of nutrient cycles, more than half of all the artificial nitrogen fertilizer ever used on Earth has been used since 1985.

Human alteration of ecosystems has had many positive effects on human health and prosperity, but it necessarily involves trade-offs. Agriculture, for example, feeds and employs huge numbers of people. But the spread of agriculture into marginal lands may degrade soils and compromise ecosystem delivery of clean water, as when overuse of artificial fertilizers results in eutrophication. Extensive use of pesticides controls insect pests, but also reduces populations of pollinators and the services they provide to both crops and native plants.

Similarly, the loss of wetlands and other natural buffers has reduced the ability of ecosystems to regulate flooding and other natural hazards. The damage from the tsunami that hit Indonesia and other Southeast Asian countries in December 2004 was greater in many places than it would have been had the mangrove forests that protect the coast not been cut down and converted to cropland. Hurricane Katrina, which struck the U.S. Gulf Coast less than a year later, would not have caused as much flooding in New Orleans had the wetlands surrounding the city been intact. Katrina's devastating effects were due in part to a situation that had been developing for decades.

New Orleans is located on the Mississippi River delta. Much of the city lies below sea level, buffered by dams and levees constructed by the Army Corps of Engineers. The upstream dams that protect New Orleans from flooding also prevent the river

from depositing the sediments that have sustained the surrounding delta wetlands for centuries. Oil and natural gas producers have cut thousands of small canals through those wetlands in order to lay pipelines and drilling rigs, and the extraction of oil and gas from beneath the land has caused it to sink. Increased dredging of shipping lanes and rising sea levels due to global warming have contributed to a rise in salinity, killing off many of the great cypress tree swamps. These extensive alterations resulted in the loss of over 80% (more than 1.2 million acres) of the delta wetlands between 1930 and 2005. By the time Katrina made landfall, those wetlands could no longer protect New Orleans from flooding. Storm surges raced along the paths carved by canals and shipping lanes to breach the levees, inundating much of the city.

As it flooded New Orleans, Hurricane Katrina raised awareness and appreciation of an ecosystem hitherto taken for granted by most people. Crucial not only for their flood control services, the delta wetlands provide winter habitat for some 70% of the migrating birds in the huge Mississippi Valley. They are also the spawning grounds for marine organisms, some of which are commercially valuable. The delta's famous shrimp industry contributes about 30% by weight of the total commercial fish harvest in the continental United States. The importance of coastal wetlands—and, indeed, of a wide range of other ecosystems—to human well-being mandates careful ecosystem management to guarantee a sustained flow of ecosystem goods and services.

58.4 RECAP

Ecosystems provide human society with indispensable goods and services. Altering ecosystems can compromise their ability to provide these goods and services.

- What are some of the essential goods and services that ecosystems provide to humans? **See p. 1238**
- How do human efforts to increase the provision of some ecosystem services cause degradation of other ecosystem services?

How can we meet the challenge of obtaining goods and services from ecosystems without compromising their ability to provide those goods and services over the long term? Fortunately, options exist for sustainable management of ecosystems.

58.5 How Can Ecosystems Be Sustainably Managed?

Practices that allow us to conserve or enhance ecosystems so as to benefit from specific ecosystem goods and services over the long term without compromising others are referred to as **sustainable**. In many cases, the total economic value of a sustainably managed ecosystem is higher than that of an intensively exploited ecosystem (**Figure 58.19**). The long-term economic benefits of preventing overexploitation of marine fish popula-

58.19 Economic Values of Sustainably Managed and Converted Ecosystems

Many types of ecosystems can provide more goods and services when they are sustainably managed than when they are converted and intensively exploited.

tions, for example, are enormous. The collapse of the cod fishery on Georges Bank due to overfishing (see Figure 55.13) resulted in the loss of tens of thousands of jobs and cost at least \$2 billion in income support and retraining, and it can take a long time for such fisheries to recover.

Impeding the establishment of policies that encourage sustainable management is the impression that ecosystem services are “public goods” with no market value. People who do not stand to profit from the goods and services provided by natural ecosystems have no incentive to pay for them, whereas individuals who own converted ecosystems can reap great eco-

nommic benefits from them. As with other “public goods,” government action may be needed to create incentives encouraging sustainable ecosystem management. Examples of such action might include:

- Elimination of subsidies that promote damaging exploitation of ecosystems. For example, the billions of dollars paid by governments in developed nations to subsidize domestic agriculture (with the hope of insulating farmers from economic risk) have led to greater food production than the global market warrants, promoted excessive use of fertilizers, and reduced the profitability of agriculture in developing countries.
- More sustainable use of fresh water could be achieved by charging users the full cost of providing the water, by developing methods to use water more efficiently, and by altering the allocation of water rights so that the incentives favor conservation.
- More sustainable use of marine fisheries could be achieved by establishing more protected marine reserves and “no-take” zones where fish can grow to reproductive age. Recent discussions of marine fisheries management center on what is colloquially known as the BOFFF hypothesis—for “Big Old Fat Female Fish”—that the largest and oldest females in a population are the most important to protect because they outproduce younger fish by an enormous margin.

Raising public awareness of endangered ecosystems is essential to the successful implementation of sustainable management programs. Most people do not understand the long-term value of ecosystem goods and services or realize how human activities affect the functioning of ecosystems, so public education programs are needed.

Maintaining and enhancing ecosystem goods and services that have no established market value is especially difficult. Probably the most difficult service to maintain in the face of increasingly intensive human use of the global ecosystem will be biological diversity. The final chapter of this book is devoted to this important topic.

CHAPTER SUMMARY

58.1 What Are the Compartments of the Global Ecosystem?

- Earth is a closed system with respect to atomic matter, but an open system with respect to energy.
- Earth’s physical environment can be divided into four compartments: atmosphere, oceans, fresh waters, and land. **Review Figure 58.1**
- Most global air circulation takes place in the lowest layer of the atmosphere, the **troposphere**. A layer of ozone in the **stratosphere** absorbs ultraviolet radiation. **Review Figure 58.2**
- Water vapor, carbon dioxide, and other **greenhouse gases** in the atmosphere are transparent to sunlight but trap heat, thus warming Earth’s surface. **Review Figure 58.3**

- Most materials that cycle through the four compartments end up in the oceans, where they eventually sink to the bottom. Cold, nutrient-rich water rises and returns nutrients to the ocean surface in coastal **upwelling zones**. **Review Figure 58.4**
- Only a small fraction of Earth’s water resides in the freshwater compartment, but water cycles rapidly through it. Nutrients reach lakes and streams by surface flow or by the movement of **groundwater**.
- **Turnover** brings nutrients and dissolved carbon dioxide to the surface and oxygen to the deeper waters of freshwater lakes. Turnover occurs regularly in temperate-zone lakes in spring in fall. **Review Figure 58.5**
- Land covers only one-fourth of Earth’s surface but is connected to the atmospheric compartment by living organisms, which

remove chemical elements from the atmosphere and release them back.

58.2 How Does Energy Flow through the Global Ecosystem?

- Net primary production varies across the globe, reflecting differences in temperature, moisture, and the distribution of land masses. **Review Figures 58.6 and 58.7**
- Humans appropriate approximately 24% of Earth's average annual net primary production, although the percentage varies regionally.

58.3 How Do Materials Cycle through the Global Ecosystem?

- The pattern of movement of a chemical element through organisms and the compartments of the global ecosystem is its **biogeochemical cycle**.
- The **hydrologic cycle** is driven by the sun, which evaporates water from ocean surface than it returns by precipitation. The excess precipitation that falls on land eventually returns to the oceans, primarily in rivers. **Review Figure 58.8, ANIMATED TUTORIAL 58.1**
- Groundwater plays a minor role in the hydrologic cycle, but is being seriously depleted by human activities.
- Carbon is removed from the atmosphere by photosynthesis and returned to the atmosphere by metabolism. The rate at which carbon moves from the atmosphere to the oceans depends in part on photosynthesis by phytoplankton. **Review Figure 58.9, ANIMATED TUTORIALS 58.2 and 58.3**
- The concentration of CO₂ in the atmosphere has greatly increased in the last 150 years, largely due to the burning of **fossil fuels**. This buildup of CO₂ is warming the global climate. **Review Figures 58.10–58.12**
- As a result of agricultural use of fertilizers and the burning of fossil fuels, total nitrogen fixation by humans is about equal to

natural nitrogen fixation. **Review Figures 58.13 and 58.14, ANIMATED TUTORIAL 58.4**

- Human alteration of the nitrogen cycle has resulted in excesses of nitrogen compounds in bodies of water, leading to **eutrophication** and “dead zones.”
- The burning of fossil fuels increases the concentrations of sulfur and nitrogen in the atmosphere, leading to **acid precipitation**. **Review Figure 58.16**
- Agricultural use of fertilizers and clearing of land have dramatically increased the input of phosphorus into soils and fresh waters. **Review Figure 58.17**

58.4 What Services Do Ecosystems Provide?

- The goods and services provided by ecosystems include food, clean water, flood control, pollination, climate regulation, spiritual fulfillment, and aesthetic enjoyment. Most ecosystem services either are irreplaceable or the technology necessary to replace them is prohibitively expensive.
- Efforts to enhance the capacity of an ecosystem to provide some goods and services often come at the cost of its ability to provide others.
- The most important driver of change in ecosystems has been changes in land use, as natural ecosystems have been converted to other, more intensive uses.

58.5 How Can Ecosystems Be Sustainably Managed?

- In many cases, the total economic value of a sustainably managed ecosystem is higher than that of a converted or intensively exploited ecosystem. **Review Figure 58.19**
- Recognition of the value of ecosystem goods and services that are now perceived as “public goods” may induce government action to protect them. Public education is needed to make people aware of how much they benefit from ecosystem goods and services and how human activities affect the ecosystems that provide them.

SEE WEB ACTIVITY 58.1 for a concept review of this chapter.

SELF-QUIZ

- Unusual features of Earth as a planet that affect its ecosystem dynamics include
 - lithospheric plates that move continuously.
 - atmospheric gases that moderate surface temperatures.
 - large amounts of water in liquid form.
 - a diversity of living organisms.
 - All of the above
- Marine upwelling zones are important because
 - they help scientists measure the chemistry of deep ocean water.
 - they bring to the surface organisms that are difficult to observe elsewhere.
 - ships can sail faster in these zones.
 - they increase marine productivity by bringing nutrients back to surface ocean waters.
 - they bring oxygenated water to the surface.
- Which of the following is *not* true of the troposphere?
 - It contains nearly all of the atmospheric water vapor.
 - It contains a layer of ozone, which filters out ultraviolet light.
 - It is about 17 kilometers thick in the tropics and subtropics.
 - Most global air circulation takes place there.
 - It contains about 80 percent of the mass of the atmosphere.
- The hydrologic cycle is driven by
 - the flow of water into the oceans via rivers.
 - evaporation (transpiration) of water from the leaves of plants.
 - evaporation of water from the surface of the oceans.
 - precipitation falling on land.
 - the fact that more water falls on the ocean as precipitation than evaporates from its surface.
- Carbon dioxide is called a greenhouse gas because
 - it is used in greenhouses to increase plant growth.
 - it is transparent to heat, but traps sunlight.
 - it is transparent to sunlight, but traps heat.
 - it is transparent to both sunlight and heat.
 - it traps both sunlight and heat.
- Iron is an essential micronutrient that
 - is insoluble in oxygenated water.
 - is abundant in rocks and minerals.
 - moves into the ocean via atmospheric dust.
 - is a limiting factor for photosynthesis in oceans.
 - All of the above

7. The biogeochemical cycle of phosphorus differs from the cycles of carbon and nitrogen in that
 - a. phosphorus lacks an atmospheric component.
 - b. phosphorus lacks a liquid phase.
 - c. only phosphorus is cycled through marine organisms.
 - d. living organisms do not need phosphorus.
 - e. The phosphorus cycle does not differ importantly from the carbon and nitrogen cycles.
8. The sulfur cycle influences the global climate because
 - a. sulfur compounds are important greenhouse gases.
 - b. sulfur compounds help transfer carbon from the atmosphere to the oceans.
 - c. sulfur compounds in the atmosphere are components of particles around which water condenses to form clouds.
 - d. sulfur compounds contribute to acid precipitation.
 - e. Both c and d
9. Acid precipitation results from human modifications of
 - a. the carbon and nitrogen cycles.
 - b. the carbon and sulfur cycles.
 - c. the carbon and phosphorus cycles.
 - d. the nitrogen and sulfur cycles.
 - e. the nitrogen and phosphorus cycles.
10. Maintaining the capacity of ecosystems to provide goods and services is important because
 - a. most ecosystem services cannot be replicated by any other means.
 - b. replacing them with technological substitutes is possible only in developed nations
 - c. technological substitutes take up valuable land.
 - d. governments cannot function without taxing ecosystem services.
 - e. It is not important. Humans could survive quite well even if ecosystem services declined greatly.

FOR DISCUSSION

1. A string of powerful hurricanes struck the east coast of the United States over the course of a single year's hurricane season. Some people claim that this disaster was due to warming of the oceans caused by greenhouse gases in the atmosphere. Others assert that global warming is not responsible because hurricanes have occurred for many centuries. How would you evaluate these conflicting claims?
2. The waters of Lake Washington, adjacent to the city of Seattle, rapidly returned to their preindustrial condition when sewage was diverted from the lake to Puget Sound, an arm of the Pacific Ocean. Would all lakes being polluted with sewage clean themselves up as quickly as Lake Washington if sewage inputs were stopped? What characteristics of a lake are most important to its rate of recovery following reduction of nutrient inputs?
3. Tropical forests are being cut down and burned at a rapid rate to clear land for agriculture. Does this necessarily mean that deforestation is a major source of CO₂ inputs to the atmosphere? Why or why not?
4. What types of experiments would you conduct to assess the likely consequences of fertilization of the oceans with iron to increase rates of photosynthesis? At what spatial and temporal scales should they be conducted?
5. A government official authorizes the construction of a large coal-burning power plant in a former wilderness area. Its smokestacks discharge great quantities of combustion wastes. List and describe all the likely effects on ecosystems at local, regional, and global levels. If the wastes were thoroughly scrubbed from the stack gases, which of the effects you have just outlined would still happen?
6. Many nations have signed the Kyoto Accord, which commits them to reducing their emissions of CO₂ to the atmosphere. This agreement, however, is set to expire in 2012. In 2009, the United Nations drafted a new treaty to control greenhouse gases, proposing a goal of reducing global average annual greenhouse gas emissions to 2 metric tons per person (in 2006, average annual emissions per U.S. citizen were 19.78 tons). One mechanism for achieving this goal is called "cap and trade," whereby a government sets a "cap," or limit, on emissions by polluters, but allows facilities that emit less than their allowance to sell their excess credits to polluters who would otherwise exceed their allowance. What are the relative benefits and drawbacks you can see to such an approach to reducing emissions?

ADDITIONAL INVESTIGATION

The experiment described in Figure 58.18 showed that interactions between elevated atmospheric CO₂ concentrations and nitrogen fixation can reduce the availability of other essential nutrients. The investigators suggested an expansion in the suite

of elements that should be studied to determine whether elevated concentrations of CO₂ are likely to result in a large carbon sink in terrestrial ecosystems. What other elements should be considered, and how might their influence be investigated?

WORKING WITH DATA (GO TO yourBioPortal.com)

Atmospheric CO₂ and Nitrogen Fixation This exercise offers further details and data from the experiments by Bruce Hungate and colleagues illustrated in Figure 58.18. You will be

asked to analyze the data and come to your own conclusions about the effects of increasing atmospheric carbon dioxide on global fixation of nitrogen by green plants.

No laughing matter

By the time the U.S. Congress passed the Endangered Species Act in 1973, Blackburn's sphinx moth (*Manduca blackburni*) was already believed to be extinct. The largest native insect in the Hawaiian Islands, with a wingspan of over 120 mm, this species was once widespread throughout the islands, occurring in dry forests from sea level up to 760 m elevation. As a caterpillar, it fed on native shrubs in the tomato family. Nobody knew exactly what led to its disappearance, but one suspect was a parasitoid wasp imported to the islands for the biological control of the tobacco hornworm (*Manduca sexta*), a close relative of Blackburn's sphinx moth that itself had been accidentally introduced to the islands and had become a pest in commercial tomato fields.

Miraculously, a population of Blackburn's sphinx moths was discovered on Maui in 1984, in an area used by the Hawaii National Guard for military training. Since that

time, several other populations have been found on the island of Hawaii and on Kaho'olawe, an island adjacent to Maui. In February 2000, Blackburn's sphinx moth became the first Hawaiian insect species to be protected under the U.S. Endangered Species Act.

To date, no Blackburn's sphinx moths have been rediscovered on the islands of Kauai or Niihau. These islands, however, are home to another endangered species, the Hawaiian alula plant (*Brighamia insignis*). This odd-shaped shrub, one of several species called by the Hawaiian name of "haha," is found in dry forests ranging from sea level to 480 m on sheer cliffs and rocky outcrops. Its bulbous stem, typically 1–2 m long, produces a whorl of leaves at the top, along with clusters of yellow flowers with petals that are fused into a trumpet-shaped tube up to 14 cm in length. Today the species persists only with the assistance of dedicated botanists and conservation biologists who hand-pol-

linate the flowers, often rappelling down steep cliff faces to do so. Its most important (and possibly only) native pollinator likely went extinct.

The long, tubular flowers are typical of those pollinated by long-tongued moths in the hawk moth family. Short of traveling back in time, there is no sure way to identify the

Extinction and Back The large Blackburn's sphinx moth (*Manduca blackburni*) was believed to be extinct, possibly the victim of mortality due to a parasitoid wasp imported to Hawaii to control the tobacco hornworm (*M. sexta*)— another imported insect. A population of *M. blackburni* was rediscovered in 1984.

One Extinction May Lead to Another The endangered Hawaiian shrub alula (*Brighamia insignis*), also known as “haha,” persists only because humans hand-pollinate the flowers; its natural pollinators may have gone extinct.

native pollinator of *B. insignis*, but evidence points to Blackburn’s sphinx moth—whose existence today hangs by a thread on islands many kilometers away, where no alula plants remain. It is no coincidence that both species are endangered.

This contemporary example of the unanticipated effects of species loss is far from unique. Given what we’ve learned about species interactions, it’s not surprising that the loss of one species from a community can result in the endangerment of another. While the effects of biodiversity losses can be difficult to predict, anticipating those effects is a high priority in view of today’s escalating rates of species extinctions.

IN THIS CHAPTER we will describe the rapidly expanding field of conservation biology, which is devoted to protecting biodiversity. We will show how conservation biologists predict changes in biodiversity and see how some human activities are causing those changes. Finally, we will describe the strategies conservation biologists use to reduce extinction rates, protect species from threats to their persistence, and help populations of endangered species recover.

CHAPTER OUTLINE

- 59.1** What Is Conservation Biology?
- 59.2** How Do Biologists Predict Changes in Biodiversity?
- 59.3** What Factors Threaten Species Persistence?
- 59.4** What Strategies Do Biologists Use to Protect Biodiversity?

59.1 What Is Conservation Biology?

Virtually all natural ecosystems on Earth have been altered by human activities. Many habitats have disappeared completely, and many others have been greatly modified. Even Earth’s climate and its great biogeochemical cycles have been altered. One consequence of these changes has been a rapid increase in the rate at which species go extinct. **Conservation biology** is an applied scientific discipline devoted to protecting and managing Earth’s biodiversity. The discipline draws heavily upon principles of ecology, ethology, and evolutionary biology, particularly with respect to elucidating the factors that determine whether a given population will persist.

Early conservation efforts were characterized by tensions between those whose principal goal was to conserve natural resources for their economic benefits and those who believed that nature has intrinsic value independent of human economic interests. Today conservation biologists study the full array of goods and services that humans derive from species and ecosystems, including aesthetic and psychological benefits. Understanding the global ecosystem and the effects of human activities on that system is now understood to be essential to the long-term well-being of *Homo sapiens*.

Conservation biology is an *applied* scientific discipline, which is to say that it involves the practical application of knowledge to solve problems. Workers in this field are guided by three basic principles:

- *Evolution is the process that unites all of biology.* To be effective in protecting and managing biodiversity, it is essential to understand the evolutionary processes that generate and maintain it.
- *The ecological world is dynamic.* Because populations and communities change continuously over time, there is no static “balance of nature” that can serve as a goal of conservation activities.
- *Humans are a part of ecosystems.* Human interests and activities must be incorporated into conservation goals and practices.

Conservation biology aims to protect and manage biodiversity

The term “biodiversity” has multiple meanings. We may speak of biodiversity as the degree of genetic variation within a species. Genetic variation can be measured as the number of alleles at a locus, the number of polymorphic loci in a genome, or

the number of individuals in a population that are polymorphic at given loci. As we have seen throughout this book, genetic variation allows organisms to adapt to environmental change. Biodiversity can also be defined in terms of species richness in a particular community. At a larger scale, biodiversity also embraces ecosystem diversity—the complex interactions within and between ecosystems. While we may study these components of biodiversity separately, in life they are intimately interconnected.

The most conspicuous manifestation of biodiversity loss is species extinction. Extinction is a constant theme in the history of life; most of the species that have lived on Earth over the ages are extinct today. Consider, for example, the anaerobic organisms that were lost as early photosynthetic prokaryotes and eukaryotes added oxygen to Earth's atmosphere, as described in Section 25.2. Extinctions have occurred throughout Earth's history at what is referred to as a "background" rate, as changes in environmental conditions favor some species and negatively affect others. But the rate of extinctions taking place today rivals those of the five great *mass extinctions* of life's history (see Table 25.1 and Figure 25.12). Those historical extinction episodes were the result of cataclysmic natural disturbances, whereas the majority of modern extinctions can be attributed to effects of the human population.

Humans have a tremendous capacity to alter ecosystems and, accordingly, to cause extinctions. When humans first arrived in North America from Siberia about 14,000 years ago, they encountered a diverse and spectacular fauna of large mammals, including saber-toothed cats, dire wolves, mammoths,

mastodons, giant ground sloths, and giant beavers (**Figure 59.1**). Most of this megafauna went extinct within a few thousand years after humans arrived. Although several hypotheses have been advanced to account for the geologically rapid, simultaneous disappearance of so many large animals, overhunting by humans is widely embraced as the principal cause. Losses of megafauna coinciding with the arrival of humans have also been documented in Australia and Hawaii.

As Chapter 25 described, several mass extinctions have occurred on Earth, each providing ecological opportunities for other groups, which subsequently underwent adaptive radiations. These extinction events occurred relatively far apart over the course of the history of life (see Figure 25.12). Over the past 400 years, increasing industrialization and urbanization have accelerated the rate of species extinctions astronomically. The renowned evolutionary biologist Edward O. Wilson estimates that Earth is losing on the order of 30,000 species per year, putting us in the midst of a sixth mass extinction. Protecting Earth's biodiversity requires maintaining the processes that generate new species as well as providing conditions that bring extinction rates closer to background levels.

Biodiversity has great value to human society

Conservation biologists are concerned about the escalating loss of Earth's biodiversity for many reasons:

- *Losing species can threaten the functioning of ecosystems.* The preceding chapters have all described the complex interactions among species. When species are lost, entire communities and ecosystems may change or be lost completely. When that happens, humans may lose the goods and services those ecosystems provide (see Section 58.4).
- *Humans depend on thousands of other species for food, fiber, and medicine.* Over 2,000 species of plants are used for fiber worldwide, and countless more have been domesticated as a source of food. In India alone, over 7,000 species of plants are utilized in traditional medicine, and in the United States more than a quarter of all medical prescriptions contain or are based on plant products. Hundreds of animal species also supply us with food, clothing, and medicine. In addition to goods provided, many organisms provide important services; a wide variety of microbes, for example, provide the fermentation services that render many foods more nutritious and palatable (see Section 51.2).
- *Humans derive enormous psychological benefits, including aesthetic pleasure, from interacting with other organisms.* Aesthetic benefits actually confer economic value on biodiversity. Trees growing on a residential lot, for example, can increase the lot's property value to a point where this added value may be greater than the lumber from the trees could provide.

59.1 Extinct North American Megafauna The extinction of some Pleistocene megafauna in North America may have been partially driven by the arrival of *Homo sapiens*. This reconstruction of California's La Brea Tar Pits shows a dire wolfe (*Canis dirus*, left) and a sabertooth tiger (*Smilodon* sp.).

- *Extinctions deprive the scientific community of opportunities to study and understand ecological relationships among organisms.* The more species that are lost, the more difficult it will be to understand the structure and functioning of ecological communities and ecosystems.
- *Living in ways that cause the extinction of other species raises ethical issues.* Losses of biodiversity increasingly concern philosophers, ethicists, and religious leaders because in such circles species are judged to have intrinsic value.

All of these concerns, to varying degrees, may be integrated by conservation biologists into strategies for protecting biodiversity.

59.1 RECAP

Conservation biology is an applied scientific discipline aimed at protecting and managing biodiversity, which is rapidly decreasing due to extinctions caused by human activities.

- Explain the distinctions among the multiple meanings of the term “biodiversity.” **See pp. 1243–1244**
- What are some of the ways in which biodiversity is valuable to humans? **See pp. 1244–1245**

To protect biodiversity, conservation biologists must understand biodiversity as it exists today as well as the ways in which it is changing. Thus one important enterprise for conservation biologists is to predict rates of species extinctions.

59.2 How Do Biologists Predict Changes in Biodiversity?

How many, and which, species will go extinct will depend both on human activities and on natural events. Conservation biologists attempt to track the extinctions that are occurring and to predict the number that will occur during the coming century.

Our knowledge of biodiversity is incomplete

Predicting extinctions is difficult for a number of reasons. First, we do not know how many species are living on Earth today. Many of the species that may go extinct in the near future have not even been named and described. Insects provide a case in point: although over 900,000 species have been described, estimates of the number of species yet to be discovered range from about 2 million to more than 50 million (see Section 32.4). Even in the case of larger organisms, our understanding of biodiversity is far from complete. For example, in an 18-month period in 2005–2006, over 50 species of animals and plants previously unknown to science were discovered in rainforests in Borneo.

Second, we do not know where species live. The ranges of most described species, particularly those that

are small, reclusive, and rare to start with, are poorly known. One tiny North American true bug, *Corixidea major* (so rare that it has no common name), had been found in only one location near Clarksville, Tennessee, until entomologists collecting insects attracted to lights at night discovered it in Virginia and Florida, extending its known range by over 1,000 km.

Third, it is difficult to determine whether a species is truly extinct. Rarely is the death of the last surviving member of a species recorded with certainty, as it was in the case of the last passenger pigeon (*Ectopistes migratorius*), a female named Martha who died in the Cincinnati Zoo on September 1, 1914. The status of rare, reclusive species with poorly known life histories is much more difficult to determine, as has been the case with the ivory-billed woodpecker (*Campephilus principalis*) in the United States (**Figure 57.2A**). Pygmy tarsiers (*Tarsius pumilus*, tiny primates weighing less than 60 grams) were thought to have gone extinct from their native cloud forests on the island of Sulewesi in Indonesia. In 2008—85 years after the last live specimen had been sighted—a research team from Texas A&M University discovered individuals of this species living in one of the island’s national parks (**Figure 57.2B**).

Fourth, we rarely know all of the connections among species. At the beginning of this chapter, we saw that the extinction of a hawk moth species put at risk the survival of a plant species dependent upon the hawk moth as a pollinator. How many other species have been placed at risk by the extinction of the hawk moth is unknown because the ecological associations of this species were not thoroughly documented before its extinction.

(A) *Campephilus principalis*

(B) *Tarsius pumilus*

59.2 Is It Really Extinct? (A) The ivory-billed woodpecker (shown here in a nineteenth-century John James Audubon print) was presumed to be extinct until reports of sightings in 2004. Clear proof of the living bird has so far eluded watchers. (B) Among vertebrates, pygmy tarsiers were recently rediscovered in Indonesia after having been declared extinct.

We can predict the effects of human activities on biodiversity

Despite these gaps in our understanding of biodiversity, methods exist for estimating probable rates of extinction resulting from human activities. To make such predictions, conservation biologists have applied the principles of the species–area relationship and the theory of island biogeography, which we discussed in Section 57.3. When they have measured the rate at which species richness decreases with decreasing habitat patch size, they have found that, on average, a 90 percent loss of habitat area results in the loss of half of the species that live in and depend on that habitat.

59.3 Deforestation Rates in Tropical Forests Less than half the tropical forest that existed in Central America in 1950 remained as of 1985, most of it in small patches. Although the rate of deforestation slowed somewhat after 1985, by 2005 an additional 19 percent had disappeared.

Similar calculations can be made for the total global area of a habitat type. The current rate of loss of tropical evergreen forest—Earth’s most species-rich biome—is about 2 percent of the remaining forest each year, due to the increasing demand for forest resources by a rapidly expanding human population (**Figure 59.3**). If this rate of loss continues, at least 1 million species that live in tropical evergreen forests could become extinct this century.

To estimate the risk that a particular population will become extinct, conservation biologists develop statistical models that incorporate information about a population’s size, its genetic variation, and the morphology, physiology, and behavior of its members. Species in imminent danger of extinction in all or most of their range are labeled *endangered*. *Threatened* species are those that are likely to become endangered in the near future.

Species with small populations face particular risks. Rarity itself is not always a cause for concern, because some species that live in unusual habitats have probably always been rare and are well adapted to being rare. However, species whose populations suddenly shrink rapidly—the “newly rare”—are usually at high risk, as such reductions in population size can lead to genetic drift and loss of genetic variation. Species with specialized habitat or dietary requirements are more likely to become extinct than species with more generalized requirements.

In addition, populations reduced to a small size or confined to a small range can easily be eliminated by local disturbances. For example, numbers of the Cozumel thrasher (*Toxostoma guttatum*), a member of the mockingbird family known only on the island of Cozumel off the coast of Mexico, had been declining for years due to a combination of factors (including the introduction of bird-eating boa constrictors to the island in 1971). A series of hurricanes, beginning with Hurricane Gilbert in 1988, had a catastrophic effect on the remaining populations. Surveys in 2006 failed to document any surviving individuals, and the species may now be extinct.

59.2 RECAP

Predicting changes in biodiversity is difficult because our knowledge of biodiversity is incomplete. The species–area relationship can be used to predict rates of extinction in areas that are subject to habitat loss.

- What are some of the gaps in our current knowledge of biodiversity? **See p. 1245**
- Why are species with rapidly shrinking populations especially vulnerable to extinction? **See p. 1246**

Now that we’ve examined some of the factors that place species at risk of extinction, let’s see how human activities contribute to those risks. We begin with habitat loss, the primary threat to species persistence today.

59.3 What Factors Threaten Species Persistence?

Human activities that threaten the persistence of species include habitat alteration, introduction of exotic species, overexploitation, and climate alteration. Conservation biologists determine how these activities affect species and use that information to devise strategies to protect species that are endangered or threatened.

Species are endangered by the degradation, destruction, and fragmentation of their habitats

Loss of suitable habitat by degradation, fragmentation, or destruction is the most important cause of species endangerment in the United States (Figure 59.4) and around the world. Many habitats—particularly freshwater habitats—are degraded by pollution. Toxic substances released by human activities have negative effects on the behavior, reproduction, and development of species, reducing both survivorship and competitive

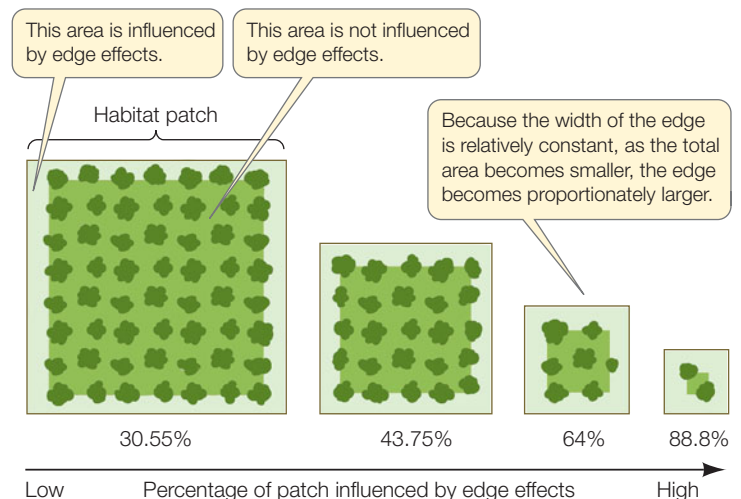

ability. Habitat loss can also occur through outright removal. Physical destruction of particular habitat types (such as tropical rainforest) eliminates species that cannot survive anywhere else. Habitat loss also affects nearby habitats that are not destroyed. As portions of a habitat are progressively lost to human activities, the remaining habitat becomes increasingly fragmented: habitat patches become smaller and more isolated.

Small habitat patches are qualitatively different from larger patches of the same habitat in ways that affect species persistence. Small patches cannot maintain populations of species that require large areas, and they support only small populations of those species that can survive in small patches. In addition, the fraction of a patch influenced by external factors increases rapidly as patch size decreases (Figure 59.5). Close to the edges of a forest patch, for example, winds are stronger, temperatures are higher, humidity is lower, and light levels are higher than they are farther inside the forest. Species from surrounding habitats often colonize edges to compete with or prey upon the species living there. The effects of such factors are known as **edge effects**.

One effect of forest fragmentation in midwestern North America has been an increase in the abundance of the brown-headed cowbird (*Molothrus ater*). This bird is a brood parasite—that is, it lays its eggs in the nests of other bird species. When a cowbird egg hatches, the hatchling is raised by the host parents, often to the detriment of their own young. Historically, cowbirds followed bison and other grazing mammals, feeding on insects kicked up by the herds; thus their eggs were laid primarily in nests of grassland host species. Forest fragmentation, however, opened up new opportunities for the cowbirds, which can now lay their eggs in the nests of forest birds in forest edges. Fragmented forests, with relatively more edge than intact forests, thus favor the proliferation of cowbirds at the expense of forest species.

59.4 Proportions of U.S. Species Extinct or Threatened The species most threatened with extinction all live in freshwater and wetlands habitats, which are highly vulnerable and have been extensively degraded, polluted, and even destroyed for human development.

59.5 Edge Effects The smaller a patch of habitat, the greater the proportion of that patch that is influenced by conditions in the surrounding environment.

59.6 Species Losses in Brazilian Forest Fragments Biologists studied patches of tropical evergreen forest near Manaus, Brazil, before and after they were isolated by forest clearing. The results of the study demonstrated that small, isolated habitat fragments support fewer species than larger patches of the same habitat.

Because so many habitats have already undergone fragmentation by the time they are first investigated by ecologists, determining the effects of fragmentation on the original communities can be difficult. Timely surveys can provide some of this information. For example, a major research project was launched in 1979 in tropical evergreen forest near Manaus, Brazil, that was slated for conversion to pasture. The landowners agreed to preserve forest patches of certain sizes and configurations laid out by biologists (**Figure 59.6**). The biologists counted the species in the future “patches” while they were still part of the continuous forest, then monitored the patches after the surrounding forest was cut. Species soon began to disappear from isolated patches. The first species to be eliminated were monkeys that travel over large areas. Army ants and the birds that follow army ant swarms also disappeared quickly.

Species that are lost from small habitat fragments are unlikely to become reestablished there because dispersing individuals are unlikely to find the isolated fragments. As Section 55.4 points out, however, a species may persist in a small patch if it is connected to other patches by habitat corridors through which individuals can disperse. Among the experimental forest fragments in Brazil, those that were completely isolated lost species more rapidly than did those that were connected to unfragmented forest by corridors. Since the experiment began, some of the pastures that surrounded the experimental fragments have been abandoned, and young forests now grow in them. Within 7–9 years of abandonment, army ants and some of the birds that follow them recolonized forest fragments connected to larger forest patches by young forests. Other birds that forage in the forest canopy also reestablished themselves. Young forest is not a suitable permanent habitat for most of these species, but they can disperse through it to find more suitable habitat.

Insight into the importance of corridors has led to new conservation initiatives, among the most notable of which is the

Yellowstone to Yukon initiative. A joint Canada–United States not-for-profit organization has as its goal sustainable management of the mountain ecosystem extending from Yellowstone National Park to the Yukon Territory. This stretch of land, the largest intact ecosystem of its kind on the planet, contains high-quality habitat for many of North America’s most imperiled animals, including grizzly bears, gray wolves, lynx, and native fish. Managing the entire region not only provides corridors to connect habitats, it also provides room for populations to shift in response to global climate change.

Overexploitation has driven many species to extinction

Although habitat loss presents a greater threat to more species today than does overexploitation, many species are still threatened by overexploitation today. Elephants and rhinoceroses are at risk in much of Africa and Asia because poachers kill them for their tusks and horns, which are used for ornaments and knife handles; in addition, some men believe that powdered rhinoceros horn boosts their sexual potency.

The principal threat to the continued survival of tigers, whose numbers have declined by over 90 percent over the past

59.7 Endangered by Exploitation (A) The principal threat to the continued survival of tigers is the use of their body parts in Asian traditional medicine. (B) The endangered Banggai cardinalfish of Indonesia’s coral reefs has been overexploited because of its value to the private aquarium trade.

century, is the use of their body parts in traditional medicine—bones to treat rheumatism, eyes to cure epilepsy, and penises to enhance virility (**Figure 59.7A**). In 2009, a bowl of tiger penis soup could be obtained for \$300 in Taiwan. There is some hope that the development of drugs for treating erectile dysfunction will reduce the incidence of poaching of these endangered species, but as yet the drugs are not widely available in Asia, where demand for animal aphrodisiacs is greatest.

Massive international trade in exotic pets and aquarium fishes, ornamental plants, and tropical forest hardwoods has also decimated many species. The Banggai cardinalfish *Pterapogon kauderni* (**Figure 59.7B**) is on the brink of extinction entirely due to the pet trade; almost a million of these critically endangered fish are hauled out of the waters near Sulawesi, Indonesia, to satisfy the demand of saltwater aquarium enthusiasts.

Invasive predators, competitors, and pathogens threaten many species

As people travel, they deliberately or inadvertently move species to regions outside their original range. Some of these exotic (non-native) species become **invasive**—that is, they reproduce rapidly, spread widely, and have negative effects on the native species of the region. As we saw in Section 55.3, species that are introduced into a region where their natural enemies are absent may reach very high population densities. Moreover, the native species in an invader's new range may not have evolved specific defenses against these new antagonists and competitors.

Invasive species are spread in a number of ways. Marine organisms have been spread throughout the oceans by ballast water from ships, taken on at the port of departure and discharged at the destination port along with its content of surviving animals and plants. The notorious zebra mussel (*Dreissena polymorpha*) is thought to have arrived in North America in this way (see Figure 55.9). The brown tree snake (*Boiga irregularis*; **Figure 59.8**) arrived on Guam in air cargo shortly after World War II. Until then, the only snake on Guam was a tiny, insect-eating species. Although brown tree snakes remained rare for 20 years, in the 1960s they began to multiply and today can be found at densities as high as 5,000 individuals per km². The snake has exterminated 15 species of land birds, including 3 found only on Guam.

Over the past 400 years, Europeans colonizing new continents deliberately introduced plants and animals to their new homes in an effort to reconstruct their familiar surroundings. Many of these introductions have had disastrous effects on native flora and fauna. In Australia, the introduction of European rabbits and foxes for sport hunting and of dogs and cats as pets led to the extermination of nearly half the small to medium-sized native marsupials over the last 100 years, by a combination of competition with rabbits and predation by foxes, dogs, and cats. Some species deliberately introduced to control other invasive species have themselves become invasive and caused further problems. One example was the case of *Manduca sexta* and its wasp parasite in Hawaii, mentioned at the opening of this chapter; another such case is that of the cane toad (*Bufo marinus*), introduced in Australia to control sugarcane pests (see Figure 55.14).

59.8 An Agent of Extinction Since it was accidentally introduced onto the tiny Pacific island of Guam, the brown tree snake (*Boiga irregularis*) has eaten 15 species of land birds to extinction.

Invasive plants may also have negative effects on ecosystems. While native plants must devote considerable energy and resources to defending themselves against native herbivores, invasive plants are less prone to attack, in part because their natural enemies have been left behind in their home range. Therefore, invasive plants can devote their resources to growth and reproduction rather than to producing defensive secondary compounds.

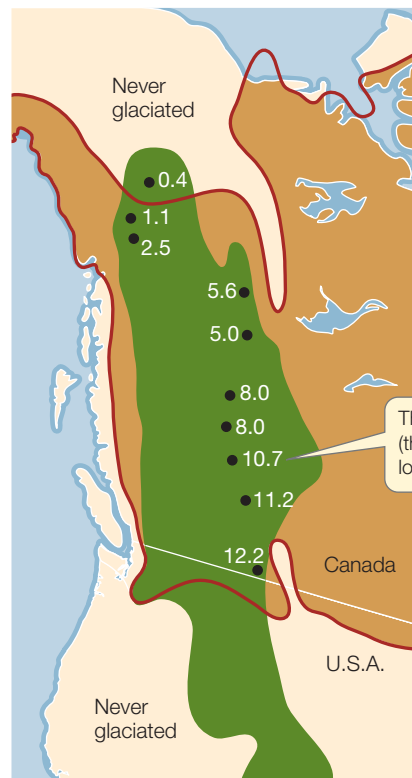

Introduced pathogens have also wreaked havoc among native species, as exemplified by the effects of avian malaria in the Hawaiian Islands. Before the arrival of Europeans, no mosquitoes existed anywhere in the islands. The first mosquito species was found there in 1827, and over the next century several others followed. At the start of the twentieth century, the microbial pathogen that causes avian malaria arrived, most likely carried by imported caged birds. Having had no exposure to malaria over the course of their evolutionary history, Hawaii's many endemic bird species were exceptionally vulnerable to infection. Today, nearly all species living below 1,500 m elevation—the current upper limit of the range of the mosquito vectors—have been eliminated by avian malaria. Species living at higher elevations have fared better, but the range of the mosquitoes appears to be expanding upward as the climate warms, placing the surviving endemic species at risk.

Rapid climate change can cause species extinctions

Human emissions of greenhouse gases are causing global climate warming, as we saw in Section 58.3. Average temperatures in North America, for example, are expected to increase 2°C–5°C by the end of the twenty-first century. If the climate warms to that extent, then the average temperature found at any given location in North America today will be found 500–800 km to the north, and species adapted to particular temperatures will have to shift their ranges by that distance, or evolve new temperature adaptations within a single century. Some habitats, such as alpine tundra, could disappear entirely as temperate forests expand up mountain slopes.

Conservation biologists cannot alter rates of global warming, but they can predict how the resulting climate changes may affect organisms and look for ways to mitigate those effects. Their research activities include analyses of past climate changes and studies of sites currently undergoing rapid climate change. It would be helpful to know, for example, how rapidly species' ranges shifted after the end of the most recent ice age, about 10,000 years ago. Which species did and did not keep pace with climate change? How much, and in what ways, did past ecological communities differ from those of today as a result of differences in the rates at which species ranges shifted?

Species that can disperse easily, such as most birds, may be able to shift their ranges as rapidly as the climate changes, provided that appropriate habitats can be found. However, the ranges of other species are likely to shift more slowly. After the glaciers retreated in North America about 8,000 years ago, for example, the ranges of some coniferous trees such as pine trees, with lightweight seeds that can be carried great distances by wind, expanded northward, so that today they grow as far north as the current climate permits (**Figure 59.9**). Earthworms, on the other hand, fared less well: the glaciers eliminated all earthworm species in Canada and the northern United States, and they have not been replaced by other North American species, which have moved their ranges northward only very slowly. (The earthworms found in many parts of North America today are actually exotic species accidentally introduced from Europe.)

- Maximum extent of glacier
- Current range of inland lodgepole pine
- Fossil sample collection site

59.9 Some Species Have Expanded Their Range Stands of lodgepole pines expanded their range northward as the continental glaciers that covered North America during the Pleistocene retreated.

If Earth's surface warms as predicted, entirely new climates will develop, especially at low elevations in the tropics, where a warming of even 2°C would result in conditions warmer than those found anywhere in the humid tropics today. Adaptation to those climates may prove difficult even for many tropical organisms. Since the mid-1980s, the average minimum nightly temperature at the La Selva Biological Station, in the Caribbean lowlands of Costa Rica, has increased from about 20°C to 22°C. On warmer nights, trees use more of their energy reserves just to maintain themselves. As a result, even this small rise in temperature has reduced the average growth rates of six different tree species by about 20 percent.

59.3 RECAP

A number of human activities threaten the persistence of species, including habitat degradation, fragmentation, and destruction; overexploitation; introductions of invasive species; and activities that cause rapid climate change.

- Describe three ways in which habitat loss is occurring today. **See pp. 1247–1248**
- Why are extinction rates high in small habitat patches? **See pp. 1247–1248 and Figures 59.5 and 59.6**
- How can dispersal ability and climate change interact to affect the probability of extinction? **See pp. 1249–1250**

Demonstrating that species are endangered is an empty exercise if we cannot implement a plan of action to save them. In the next section we consider some of the positive steps that can be taken to protect biodiversity.

59.4 What Strategies Do Biologists Use to Protect Biodiversity?

Conservation biologists use scientific theory, empirical data, and tools from a variety of disciplines to help protect endangered and threatened species and ecosystems. They identify the factors that present risks to species and use that information to devise action plans. Implementing those plans, however, often requires the cooperation of many different groups of people, so conservation biologists also work with landowners, politicians, lawyers, environmental activists, and the general public. Let's look at some of the actions that conservation biologists take to protect biodiversity.

Protected areas preserve habitat and prevent overexploitation

The establishment of *protected areas* in which habitat alteration and exploitation are restricted or prohibited is an important

component of efforts to conserve biological diversity. Protected areas preserve habitat and may serve as nurseries from which individuals can disperse into exploited areas, replenishing populations that might otherwise become extinct.

Deciding which areas to protect is a challenging enterprise. Two robust criteria are the total number of species living in an area (its *species richness*; see Chapter 57) and the number of *endemic species* in an area (a measure of its uniqueness). Using these criteria, biologists have identified a number of biodiversity “hotspots” of unusual richness and endemism (**Figure 59.10**). Hotspots occupy only 15.7 percent of Earth's land surface but are home to 77 percent of its terrestrial vertebrate species. Most hotspots are also areas of high human population density, so habitat loss is ongoing. Developing a conservation strategy for any of these regions requires not only a detailed analysis of the distributions of species and the locations of special resources (such as caves, freshwater springs, or migratory

(A) Tropical rainforest hotspots

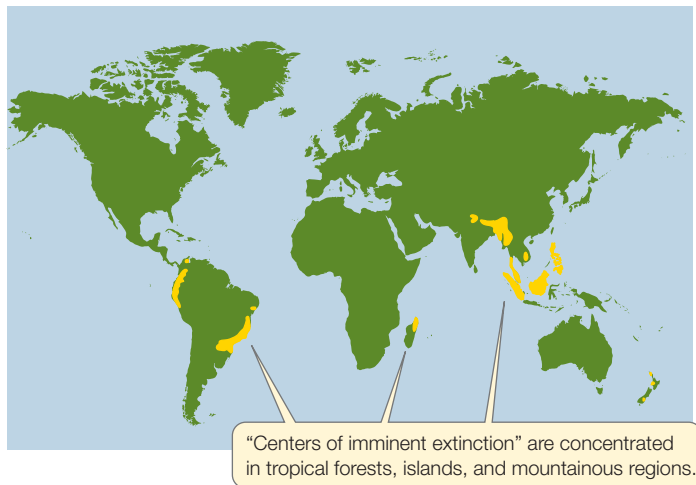

(B) Hotspots in other biomes

59.10 Hotspots of Biodiversity

(A) Almost half of the world's highest priority “hotspots” for biodiversity protection are regions of tropical rainforest habitat. Areas circled in red encompass island groups. The circled letters represent the only three remaining areas of extensive unbroken rainforest: S, South American Amazonia; C, the Congo Basin of Africa; and N, the island of New Guinea. (B) Eighteen hotspots representing other (non-rainforest) ecosystems.

59.11 Centers of Imminent Extinction The areas shown in yellow include 595 "centers of imminent extinction." These regions are home to 794 species that are at serious risk of extinction.

stopover areas for birds), but also an analysis of factors that threaten and factors that support biodiversity in the region.

In an effort to further pinpoint sites with threatened species that are found nowhere else, in 2005 conservation biologists identified 595 "centers of imminent extinction." These sites are concentrated in tropical forests, on islands, and in mountainous regions (**Figure 59.11**). Only one-third of the sites are legally protected, and most of them are surrounded by land that is undergoing rapid development. Unless protective actions are taken soon, species extinctions are inevitable.

Degraded ecosystems can be restored

When a species is endangered as a consequence of ecosystem degradation rather than outright habitat loss, protecting the species may require restoring the habitat to a more natural state. Practitioners of **restoration ecology** are developing methods aimed at just such reconstitution, because many degraded ecosystems recover only slowly, if at all, without human assistance.

Because the soil that supports them is so rich, grasslands all over the world have been converted to agriculture. By the middle of the twentieth century, for example, most North American prairies had been converted to cropland or were heavily grazed by domestic livestock. The herds of large mammals that roamed the prairies when European settlers arrived have been reduced to tiny remnants confined to small areas. Most of these remaining populations are too small to maintain their genetic diversity or play their original ecological roles. The species *have* survived, however, so opportunities exist to reintroduce them if their habitat can be restored.

A major prairie restoration project is under way in northeastern Montana. When Lewis and Clark mapped this region 200 years ago, they saw large herds of bison, elk, deer, and pronghorn, as well as abundant populations of their predators. The goal of the restoration project, run by the World Wildlife Fund and the American Prairie Foundation in cooperation with public land managers, is to restore the native prairie and its fauna in a 15,000-km² area near the Missouri River (**Figure 59.12**).

This ambitious project is feasible for three reasons. First, the private land in the area is owned by a small number of ranchers, each of whom owns extensive grazing leases on public lands administered by either U.S. federal agencies or the State of Montana. Second, most of the land has never been plowed, so native vegetation can recover rapidly when grazing pressures are reduced. Third, the area's human population is decreasing. The ranchers are aging, and their children are abandoning the hard work and uncertain profits of ranching for careers in urban settings. Once a free-ranging herd of several thousand bison and large numbers of elk—along with their predators (wolves)—has been established, nature-minded tourists are expected to flock to the area to view the wildlife spectacle. Over the long term, the restored ecosystem should deliver major economic benefits to the region.

59.13 A Wetlands Laboratory Tijuana Estuary, near San Diego, is a shallow-water wetlands habitat. Experiments at this natural research reserve shed light on ways to restore this valuable ecosystem.

In the United States, the notion that humans are capable of creating functioning replacement ecosystems underlies policies that allow developers to destroy habitats. Destruction of wetlands in particular is often permitted because of developers' assertions that they can be replaced. However, creating new wet-

lands requires detailed ecological knowledge that almost invariably far surpasses that which is currently available.

In southern California, where 90 percent of the coastal wetlands have been destroyed, wetland restoration is a high priority. Species have been lost from degraded coastal wetlands, so restoration requires species introductions. Early attempts, in which one or two common wetland species were introduced, did not succeed—other wetland-associated species failed to recolonize the “rehabilitated” wetlands. To understand why, conservation biologists established a large field experiment at the Tijuana Estuary (**Figure 59.13**). Here they found that experimental plots planted with species-rich mixtures developed a more complex vegetation structure (which is important to insects and birds) and also accumulated nitrogen (required for plant growth) faster than did species-poor plots (**Figure 59.14**).

Disturbance patterns sometimes need to be restored

Many species depend on particular patterns of disturbance—such as fires, windstorms, or grazing—to maintain their populations (see Section 57.4). Recognition of the need for periodic disturbance to maintain healthy ecosystems is a rather new dimension of conservation biology. For example, although many

INVESTIGATING LIFE

59.14 Species Richness Enhances Wetland Restoration

When biologists attempted to restore degraded areas of the Tijuana Estuary, they found that several measures of wetland ecosystem health improved more rapidly in species-rich than in species-poor plantings.

HYPOTHESIS When attempting to restore degraded wetlands, planting a mixture of species will approach the ecosystem's original condition more rapidly than planting a single species.

METHOD

1. Delimit experimental plots of degraded wetland habitat, leaving control plots unplanted (i.e., no human intervention).
2. Plant some experimental plots with a single plant species typical of wetlands in the region. Plant other plots with randomly chosen assemblages of 3 and of 6 typical species. Plant the same density of seedlings in all plots.
3. Over the subsequent 18 months, replant and weed the experimental tracts as necessary to compensate for early mortality of seedlings.

RESULTS

In the plots with higher species richness, more of the ground was covered by plants, the vegetation structure was more complex, and more nitrogen accumulated in the soil.

CONCLUSION Planting a rich mixture of species should enhance wetland restoration attempts.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

plant species require periodic fires for successful establishment and survival, for many years the official policy of the U.S. Forest Service, symbolized by the iconic mascot Smokey Bear, was to suppress all forest fires. Today, however, controlled burning is common, particularly in western North America. In order to use fire as an ecosystem management tool, it is important to know the historical pattern of fires in an area, which can be determined in part by studies of annual growth rings of trees (**Figure 59.15**). A schedule of controlled burning that recreates the historical pattern can reduce forest floor litter, avoiding a buildup of fuel that can lead to intense, tree-killing canopy fires.

Ending trade is crucial to saving some species

Most endangered species cannot survive any further reductions in their breeding populations, so it is important to prevent their exploitation. The legal mechanism for prohibiting trade in these species or their products is an international agreement called the Convention on International Trade in Endangered Species (CITES). Most nations of the world are members of CITES. National representatives meet every two years to review the status of species on the CITES protected species lists, to determine which species may no longer need protection, and to add new species. CITES rules currently prohibit international trade in items such as whale meat, rhinoceros horn, and many species of parrots and orchids.

CITES instituted a ban on international trade in elephant ivory in 1989, but demand for ivory remains strong, especially in Japan and China. As a result, poaching of elephants continues in the forests of central Africa and in East Africa, where the animals are threatened. Southern African countries

(Botswana, Namibia, South Africa, Zambia, and Zimbabwe), however, have so many elephants that government officials must kill many of them to control populations in the limited areas where they are allowed to roam to prevent them from dispersing to populated areas and damaging crops. These countries would like to sell the ivory from the culled elephants to fund their conservation efforts. Other countries are worried that if trade restrictions on ivory are relaxed, poaching will escalate over the entire continent.

Control and regulation of ivory trade might be possible if scientists could determine where the ivory comes from. Samuel Wasser and his colleagues at the University of Washington have identified 16 DNA markers that can be extracted from elephant feces. Park rangers in Malawi and Zambia were able to sample the elephant populations in their countries by collecting fresh scat while they were on routine patrols. The source of an elephant tusk can then be determined by matching DNA extracted from the ivory with the geographically based frequencies of the 16 DNA markers found in the dung samples. In June 2002, 6.5 tons of illegal ivory were seized in Singapore. DNA analyses showed that the elephants were killed in Zambia.

Such safeguards were partially responsible for the controversial decision to sanction legal sales of ivory from Namibia, Botswana, Zimbabwe, and South Africa beginning in 2008, the first such sale in close to a decade. Over 100 tons of elephant tusks, the equivalent of over 20,000 dead elephants, were auctioned off over a 2-week period to authorized buyers from China and Japan, for use primarily in folk medicine. The sale of this ivory, all of which was obtained legally from animals that had died of natural causes, generated over \$15 million for elephant conservation efforts. Although the sales were monitored by CITES, and although the last sanctioned sale, in 1999, did not appear to increase poaching activities, other African nations and many wildlife conservation groups are concerned that in the absence of oversight and enforcement, the flood of legal ivory will be intermingled with poached ivory in international markets and encourage more illegal elephant slaughter.

One promising development in curbing illegal sales was the decision by eBay, the international online marketplace, to ban sales of ivory on its platform effective January 2009. An investigation by the International Fund for Animal Welfare revealed that two-thirds of online sales of protected wildlife products take place on eBay, so conservationists are optimistic that eBay's actions will be effective in drying up markets and protecting elephants from poaching.

Invasions of exotic species must be controlled or prevented

Controlling invasions of exotic species is an important component of conservation biology. The best way to reduce the damage caused by invasive species, of course, is to prevent their introduction in the first place. Given the tremendous volume of global trade, it might seem impossible to curtail their spread. Some promising strategies, however, do exist. For example, transoceanic transport of invasive species in ballast water could be largely eliminated by the simple procedure of deoxygenat-

ing ballast water before it is pumped out. This practice not only kills most organisms in the water, but also extends the life of ballast tanks, providing an economic benefit to shippers. Although the U.S. House of Representatives passed (by a vote of 395 to 7) a Coast Guard funding bill with language stipulating that freighters operating in the Great Lakes must disinfect their ballast water, the Senate vote has been impeded by legal wrangling. In the absence of federal regulation, some states have already implemented their own ballast water treatment regulations.

Regulating the importation and sale of exotic species can reduce deliberate introductions. In 2002, some members of the American horticulture industry crafted a voluntary code of conduct for their profession, stating that the invasive potential of a plant should be assessed prior to its introduction and marketing. Horticulturists will work with conservation biologists to determine which species are currently invasive, or likely to become so, and to identify suitable alternative species. Stocks of invasive species will be phased out, and gardeners will be encouraged to use noninvasive plants.

Conservation biologists have developed a decision tree, based on the traits that characterize plant species that have become invasive, to help horticulturists and regulators determine whether an exotic plant species should be allowed into North America (Figure 59.16). Although the protocols stipulated by this decision tree cannot eliminate all introductions of invasive species, if they are followed conscientiously, they can greatly reduce the risk of such introductions.

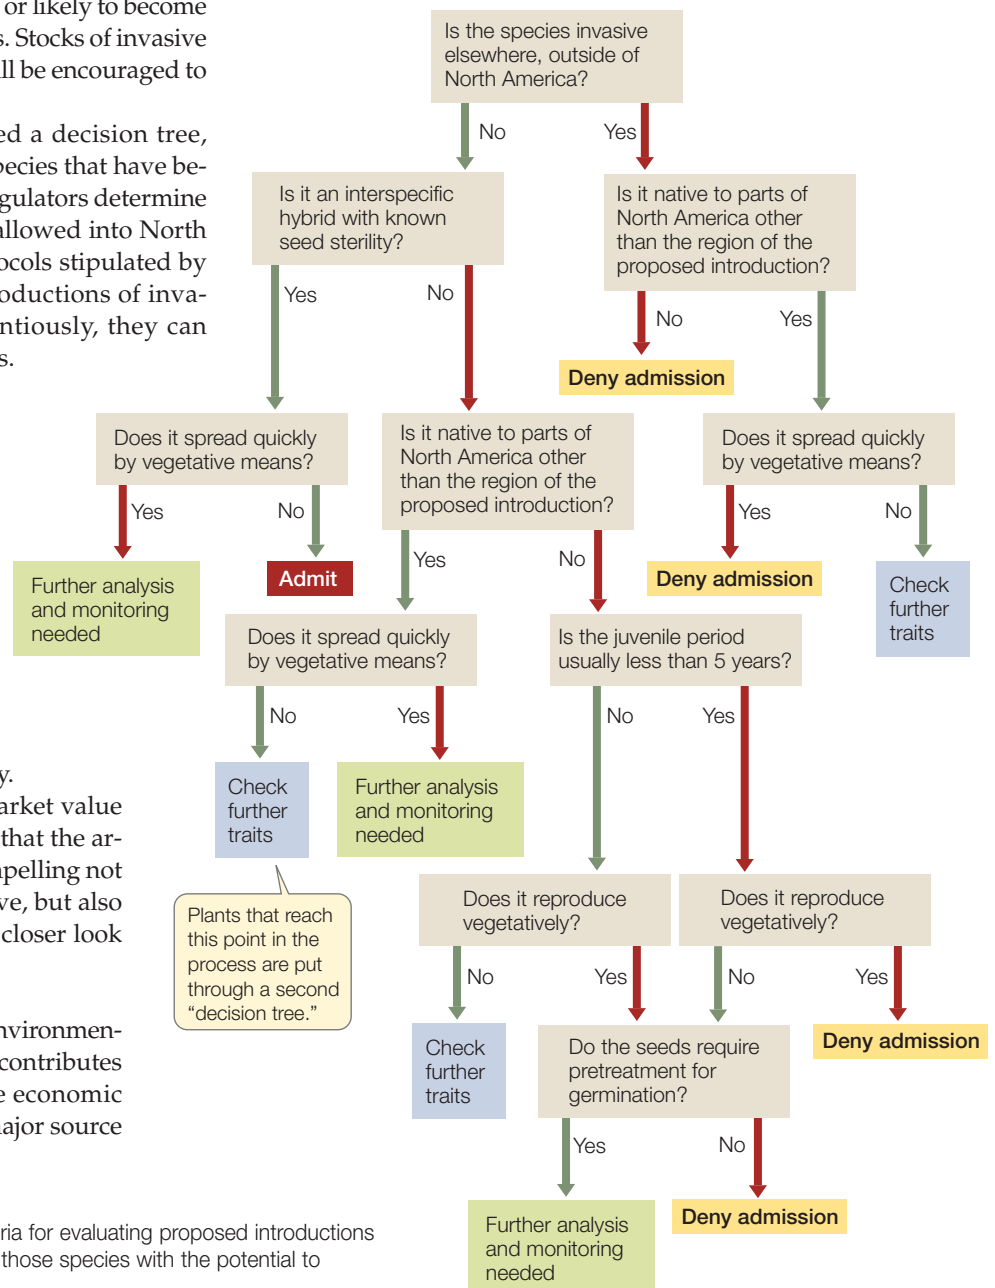

Biodiversity can have market value

Much of the value of ecosystems to human society depends on their biodiversity, but it has been difficult to assess the value of biodiversity in monetary terms. When biodiversity is perceived to have economic value, industries and government agencies have a greater incentive to protect it. The interdisciplinary field of *ecological economics* has provided tools for assessing the economic value of biodiversity.

Many studies have demonstrated the market value of protecting biodiversity. Such cases show that the argument for biodiversity conservation is compelling not only from an ecological or ethical perspective, but also from an economic perspective. Let's take a closer look at two of them.

WILD DOGS AND ECOTOURISM *Ecotourism*—environmentally responsible travel to natural areas that contributes to conserving their biodiversity and to the economic well-being of the local communities—is a major source

of income for many developing nations. For example, tourists visiting Africa often express interest in seeing wild dogs (*Lycaon pictus*; Figure 59.17). However, diseases such as rabies and canine distemper, along with habitat loss, road traffic, deliberate extermination due to a perceived threat to livestock, and many other factors, have decimated wild dog populations throughout the continent, making them the second most endangered carnivore in Africa. Once found in 39 countries, they are today found in only 14 countries. Their endangered status has piqued interest among tourists in catching glimpses of these charismatic animals. South Africa is home to about 400 of Africa's remaining 5,000 dogs, most of which live in Kruger National Park. A survey of visitors to South Africa revealed that nearly three-fourths of them would be willing to pay an extra U.S. \$12 for the opportunity to see wild dogs. Conservation biologists are

59.16 A "Decision Tree" This diagram sets criteria for evaluating proposed introductions of exotic plant species and helps regulators identify those species with the potential to become invasive.

working with lodge owners and ranchers elsewhere in South Africa and in Kenya to encourage them to reestablish wild dogs in areas from which they have disappeared.

THE FYNBOS Studies by a group of economists, ecologists, and land managers have attempted to calculate the value of the economic benefits provided by the spectacularly species-rich shrubland community called *fynbos* in the Western Cape Province of South Africa (Figure 59.18A). Of the 8,500 plant species in this region, over two-thirds are endemics. Fynbos plants thrive despite the summer droughts, nutrient-poor soils, and periodic fires of the region.

The highlands where fynbos vegetation thrives provide about two-thirds of the Western Cape's water supply. In addition, some of the endemic plants, including proteas, are harvested for cut and dried flowers. An international market has developed for rooibos, a fynbos shrub used for herbal tea. Income also comes from hundreds of thousands of ecotourists who visit the region every year to see the fynbos. The fynbos also provides recreational opportunities for local residents in urban areas nearby.

Recently, several trees and shrubs from other continents have invaded the fynbos. Taller and faster-growing than the endemics, they displace the native vegetation, in the process increasing the intensity and severity of fires. Moreover, because the invaders transpire more water than the endemics, they decrease stream flows to less than half those from areas covered with native plants, reducing the water supply for people in the region (Figure 59.18B).

We can get an idea of the market value of fynbos biodiversity by estimating the cost of maintaining or replacing the services it provides. Removing the exotic plants by felling and digging out invasive trees and shrubs and by managing fire costs between \$140 and \$830 per hectare, depending on the densities of the invaders. Alternatively, the services provided by fynbos vegetation could be replaced, but only at a much higher cost. A sewage purification plant that would deliver the same amount of water to the Western Cape as a well-managed watershed of 10,000 hectares would cost \$135 million to build and \$2.6 million per year to operate. Desalination of seawater would cost four times as much. Thus the available alternatives would deliver water at a cost between 1.8 and 6.7 times higher than the cost of maintaining natural vegetation in the watershed. Maintaining the fynbos vegetation would be less expensive and more labor-intensive (generating more employment) than the technologically sophisticated methods that could substitute for the services it provides.

Simple changes can help protect biodiversity

Establishing protected areas is an essential component of efforts to maintain biodiversity, but this action alone is insufficient to stem global biodiversity loss. The extensive landscapes in which people live and extract resources must also play important roles in biodiversity conservation. The good news is that, carefully used, these lands can contribute much more to conservation than they currently do. The practice of using ecosystems for residences, resources, or recreation in ways that sustain their biodiversity is known as **reconciliation ecology**.

Lycaon pictus

59.17 A Sight for Travelers' Eyes Tourists visiting Africa to experience its wildlife often express a desire to see the rare African wild dogs. Protecting such species can be in the economic interest of the region.

59.18 Biodiversity Maintains Ecosystem Functioning (A) The unique fynbos ecosystem of the Western Cape Province of South Africa provides much of the area's water. (B) A computer simulation of stream flows from fynbos watersheds that have and have not been invaded by exotic trees and shrubs.

Reconciliation ecology is based on the principle that most ecosystem services are provided locally, and that people are more motivated to work to protect their local interests than they are to work on national or global issues. The National Wildlife Federation has established a very successful program in which people petition to have their backyards certified as wildlife-friendly. Criteria for certification include planting shrubs that provide food for birds and refraining from applying pesticides on lawns. The city of Tucson, Arizona, has launched a major project to make the city a suitable habitat for many species of birds, not just the typical urban birds that live in most cities in North America.

Even some industrial sites can support biodiversity. The Turkey Point power plant in southern Florida uses large amounts of water to cool its generating units. To cool the heated water before discharging it, the Florida Power & Light Company dug a system of 38 canals that covers 6,000 acres. These cooling canals are separated by low-lying berms that support a variety of native and exotic plants. Red mangroves grow along the edges of the canals. Today, they support a thriving population of American crocodiles, a highly endangered species. Crocodiles living in the canals yield about 10 percent of all young crocodiles in the United States. Having discovered the biodiversity value of its cooling system, the company employs biologists to monitor the crocodiles and works actively to ensure their continued reproductive success.

Captive breeding programs can maintain a few species

A few of the world's many endangered species can be maintained in captivity while the external threats to their existence are reduced or removed. However, captive propagation is only a temporary measure that buys time to deal with those threats. Zoos, aquariums, and botanical gardens do not have enough space to maintain adequate populations of more than a small fraction of Earth's rare and endangered species. Nonetheless, captive propagation can play an important role by maintaining

species during critical periods, providing a source of individuals for reintroduction into the wild, and raising public awareness of threatened and endangered species.

The California condor, North America's largest bird, survives today only because of captive propagation (**Figure 59.19**). Two centuries ago, condors ranged from British Columbia to northern Mexico, but by 1978, the wild population was plunging toward extinction. Many of the birds, which are scavengers, died from ingesting animal carcasses containing lead shot. To save the condor from certain extinction, biologists captured all known remaining condors, which numbered only 22 individuals, and initiated a captive breeding program in 1983.

The first captive-bred birds were released in the mountains north of Los Angeles in 1992. Since that time, captive-bred birds have also been released in northern Arizona and Baja California. These birds are provided with lead-free food in remote areas, and they are trained to avoid power lines prior to release, thereby reducing a major source of mortality. Today, the captive-bred birds use the same roosting sites, bathing pools, and mountain ridges that their wild-born predecessors did. In December 2008, there were 327 known condors in the world, half of which were living in the wild. In 2003, a wild-born chick fledged in the wild for the first time in over two decades.

Most of the major threats to condor survival, including power lines, pesticides, and museum collectors, have been mitigated. Lead poisoning is still a problem, but as of July 1, 2008, under the Ridley–Tree Condor Preservation Act, California hunters are required to use non-lead bullets when hunting within the condor's range. Passage of this legislation marks a change in public attitudes from the days when cattle ranchers, in the mistaken belief that the birds killed livestock, vociferously opposed their reintroduction into the wild.

The legacy of Samuel Plimsole

During the nineteenth century, many British merchant ships sailed the world's oceans. Once these ships left harbor, they

(A)

(B) *Gymnogyps californianus*

59.19 A California Condor Soars (A) California condors raised in captivity are fed by humans wearing hand puppets so they will not imprint on their captors and will be able to survive in the wild. (B) Numbered wing tags allow conservation biologists to identify and track released adult condors. The survival of North America's largest bird species depends on this captive propagation project.

were out of contact with the rest of the world; in the case of a shipwreck, signaling for rescue was impossible. But ship owners could maximize their profits by overloading their ships, even though this practice caused some of them to become unseaworthy and sink.

Samuel Plimsoll, a member of Parliament, became concerned about the rate of loss of British vessels and sailors. He convinced Parliament to pass legislation requiring that a “load line” be painted on the hull of every large oceangoing vessel. The position of the line was calculated using factors such as the structural strength of the vessel and the shape of its hull. If the load line was under water, the ship was not permitted to leave the harbor. The “Plimsoll line,” as it came to be known, dramatically reduced the rate of loss of British ships and sailors. In 1930, the international community agreed on universal adoption of load line regulations.

The increasing loss of Earth’s species suggests that the load of human activities has pushed the planet below its Plimsoll line. But where and how should society draw that line? Our decision should be based on scientific information, but, just as in Samuel Plimsoll’s time, science cannot determine an “acceptable rate of loss.” Ethical considerations will figure prominently

in the decisions we make about changing the way we use ecosystems so that other species can survive on Earth with us.

59.4 RECAP

To conserve biodiversity, it is necessary to set aside protected areas, restore ecosystems and natural disturbance patterns, restrict trade in endangered species and transport of invasive species, increase populations of endangered species, and otherwise recognize the benefits of maintaining functioning ecosystems.

- What are some of the priorities conservation biologists consider when establishing protected areas? **See pp. 1251–1252 and Figures 59.11–59.13**
- Explain the difference between restoration ecology and reconciliation ecology. **See pp. 1252 and 1257**
- Do you think the analogy of the Plimsoll line is a good one to apply to protecting the world’s biodiversity? Why or why not?

CHAPTER SUMMARY

59.1 What Is Conservation Biology?

- **Conservation biology** is an applied scientific discipline devoted to protecting and managing biodiversity.
- Conservation biologists recognize that an understanding of the evolutionary processes that generate biodiversity is essential to protecting it. They also understand that ecosystems are dynamic, and that humans are part of those ecosystems.
- Species extinctions have always occurred, but today they are occurring at an alarming rate.
- There are many compelling reasons for protecting biodiversity, including the maintenance of the ecosystems whose many functions provide humans with goods and services, including air and water purification.

59.2 How Do Biologists Predict Changes in Biodiversity?

- Our understanding of biodiversity is incomplete. We do not know how many species there are, where they live, or which of the species known to science have gone extinct.
- Biologists can use the species–area relationship and the theory of island biogeography to estimate rates of extinction likely to be caused by habitat loss.
- To estimate a species’ risk of extinction, statistical models take into account data on population sizes, genetic variation, physiology, morphology, and behavior.
- Rarity is not always a cause for concern, but species whose populations are shrinking rapidly are usually at risk of extinction.

59.3 What Factors Threaten Species Persistence?

- Habitat loss is the most important cause of species endangerment worldwide. As habitats become increasingly fragmented, more species are lost from those habitats. Small habitat patches can support only small populations and are adversely influ-

enced by **edge effects**. **Review Figures 59.5 and 59.6, ANIMATED TUTORIAL 59.1**

- Overexploitation has historically been the most important cause of species extinctions, and it is still a major threat to biodiversity today.
- Some species introduced to regions outside their original range become **invasive**, causing extinctions of native species by competing with them, eating them, or transmitting diseases to them.
- Climate is likely to become an increasingly important cause of extinctions for those species that cannot shift their ranges as rapidly as the climate warms. **Review Figure 59.9**

59.4 What Strategies Do Biologists Use to Protect Biodiversity?

- Establishing protected areas is crucial to conserving biodiversity. Protected areas are selected by taking into account species richness, endemism, imminence of threats, and the need to protect representative ecosystems.
- **Restoration ecology** is an important conservation strategy because many degraded ecosystems will not recover, or will do so only very slowly, without human assistance. **Review Figure 59.15**
- International trade in endangered species is controlled by regulations that most countries endorse.
- Conservation biologists work to determine which species are likely to become invasive and prevent their introduction to new areas.
- Even within landscapes where people live and extract resources, steps may be taken to protect biodiversity. This approach is known as **reconciliation ecology**.
- Captive breeding programs can maintain some endangered species for the short term while threats to their persistence are reduced or removed.

SEE WEB ACTIVITY 59.1 for a concept review of this chapter.

SELF-QUIZ

- Which of the following is *not* currently a major cause of species extinctions?
 - Habitat destruction
 - Rising sea levels
 - Overexploitation
 - Introduction of exotic predators
 - Introduction of exotic pathogens
- The most important cause of endangerment of species in the United States currently is
 - climate change.
 - invasive species.
 - overexploitation.
 - habitat loss.
 - loss of mutualists.
- Species extinctions matter to human society because
 - more than a quarter of the medical prescriptions written in the United States contain a plant product.
 - people derive aesthetic pleasure from interacting with other organisms.
 - causing species extinctions raises serious ethical issues.
 - biodiversity helps maintain valuable ecosystem services.
 - All of the above
- As a habitat patch gets smaller, it
 - cannot support populations of species that require large areas.
 - supports only small populations of many species.
 - is influenced to an increasing degree by edge effects.
 - is invaded by species from surrounding habitats.
 - All of the above
- A plant species is most likely to become invasive when introduced to a new area if it
 - grows tall.
 - has become invasive in other places where it has been introduced.
 - is closely related to species living in the area where it has been introduced.
 - has specialized disseminators of its seeds.
 - has a long life span.
- Global warming is a concern because
 - the rate of change in climate is projected to be faster than the rate at which many species can shift their ranges.
 - it is already too hot in the tropics.
 - climates have been so stable for thousands of years that many species lack the ability to tolerate variable temperatures.
 - climate change will be especially harmful to rare species.
 - None of the above
- Scientists can determine the historical frequency of fires in an area by
 - examining charcoal in sites of ancient villages.
 - measuring carbon in soils.
 - radioactively dating fallen tree trunks.
 - examining fire scars in growth rings of living trees.
 - determining the age structure of forests.
- Captive propagation is a useful conservation tool, when
 - there is space in zoos, aquariums, and botanical gardens for breeding a few individuals.
 - the areas of origin of the captive individuals are known.
 - the threats that endangered the species are being alleviated so that captive-reared individuals can later be released back into the wild.
 - there are sufficient caretakers.
 - None of the above; captive propagation should never be used because it directs attention away from the need to protect the species in their natural habitats.
- Restoration ecology is an important field because
 - many areas have been highly degraded.
 - many areas are vulnerable to global climate change.
 - many species suffer from demographic stochasticity.
 - many species are genetically impoverished.
 - fire is a threat to many areas.
- The field of reconciliation ecology has developed because
 - all other methods of preserving biodiversity have failed.
 - protected areas should be able to maintain biodiversity.
 - protected areas alone are insufficient to maintain biodiversity.
 - scientists are unable to control diseases today.
 - we are not reconciled with other species.

FOR DISCUSSION

- Most species driven to extinction by humans in the past were large vertebrates. Do you expect this pattern to persist into the future? If not, why not?
- Conservation biologists have debated extensively which is better: many small protected areas (which may contain more species) or a few large protected areas (which may be the only ones that can support populations of species that require large areas). What ecological processes should be evaluated in making judgments about the sizes and locations of protected areas?
- During World War I, doctors adopted a “triage” system for dealing with wounded soldiers. The wounded were divided into three categories: those almost certain to die no matter what was done to help them, those likely to recover even if not assisted, and those whose probability of survival was greatly increased if they were given immediate medical attention. Limited medical resources were directed primarily at the third category. What are some implications of adopting a similar attitude toward species preservation?
- Utilitarian arguments dominate discussions about the importance of preserving biological richness. In your opinion, what role should ethical and moral arguments play?
- The desert bighorn sheep of the southwestern United States is endangered. Its major predator, the puma, is also threatened in the region. Under what conditions, if any, would it be appropriate to suppress the population of one rare species to assist another rare species?

ADDITIONAL INVESTIGATION

Pollination by forest-dwelling bees was found to increase seed production in coffee plants growing within a kilometer of a forest patch in Costa Rica. What forest organisms are likely to provide other benefits (such as control of insect pests) to nearby

agricultural crops? Over what distances are those effects likely to be felt? What experiments could be designed to test the importance of those effects and how they vary with distance from forest patches?

Appendix A: The Tree of Life

Phylogeny is the organizing principle of modern biological taxonomy. A guiding principle of modern phylogeny is *monophyly*. A monophyletic group is considered to be one that contains an ancestral lineage and *all* of its descendants. Any such group can be extracted from a phylogenetic tree with a single cut.

The tree shown here provides a guide to the relationships among the major groups of extant (living) organisms in the tree of life as we have presented them throughout this book. The position of the branching “splits” indicates the relative branching order of the lineages of life, but the time scale is not meant to be uniform. In addition, the groups appearing at the branch tips do not necessarily carry equal phylogenetic “weight.” For example, the ginkgo [63] is indeed at the apex of its lineage; this gymnosperm group consists of a single living species. In contrast, a phylogeny of the eudicots [55] could continue on from this point to fill many more trees the size of this one.

The glossary entries that follow are informal descriptions of some major features of the organisms described in Part Seven

of this book. Each entry gives the group’s common name, followed by the formal scientific name of the group (in parentheses). Numbers in square brackets reference the location of the respective groups on the tree.

It is sometimes convenient to use an informal name to refer to a collection of organisms that are not monophyletic but nonetheless all share (or all lack) some common attribute. We call these “convenience terms”; such groups are indicated in these entries by quotation marks, and we do not give them formal scientific names. Examples include “prokaryotes,” “protists,” and “algae.” Note that these groups cannot be removed with a single cut; they represent a collection of distantly related groups that appear in different parts of the tree. We also use quotation marks here to designate two groups of fungi that are not believed to be monophyletic.

An interactive version of this tree, with links to much greater detail (such as photos, distribution maps, species lists, and identification keys), can be found at yourBioPortal.com.

– A –

acorn worms (*Enteropneusta*) Benthic marine hemichordates [120] with an acorn-shaped proboscis, a short collar (neck), and a long trunk.

“algae” A convenience term encompassing various distantly related groups of aquatic, photosynthetic chromalveolates [5] and certain members of the Plantae [8].

alveolates (*Alveolata*) [7] Unicellular eukaryotes with a layer of flattened vesicles (alveoli) supporting the plasma membrane. Major alveolate groups include the dinoflagellates [52], apicomplexans [53], and ciliates [54].

amborella (*Amborella*) [60] An understory shrub or small tree found in New Caledonia. Thought to be the sister-group of the remaining living angiosperms [14].

ambulacrarians (*Ambulacraria*) [30] The echinoderms [119] and hemichordates [120].

amniotes (*Amniota*) [37] Mammals, reptiles, and their extinct close relatives. Characterized by many adaptations to terrestrial life, including an amniotic egg (with a unique set of membranes—the amnion, chorion, and allantois), a water-repellant epidermis (with epidermal scales, hair, or feathers), and, in males, a penis that allows internal fertilization.

amoebozoans (*Amoebozoa*) [85] A group of eukaryotes [4] that use lobe-shaped pseudopods for locomotion and to engulf food. Major amoebozoan groups include the loboseans, plasmodial slime molds, and cellular slime molds.

amphibians (*Amphibia*) [129] Tetrapods [36] with glandular skin that lacks epidermal scales, feathers, or hair. Many amphibian species undergo a complete metamorphosis from an

aquatic larval form to a terrestrial adult form, although direct development is also common. Major amphibian groups include frogs and toads (anurans), salamanders, and caecilians.

amphipods (*Amphipoda*) Small crustaceans [117] that are abundant in many marine and freshwater habitats. They are important herbivores, scavengers, and micropredators, and are an important food source for many aquatic organisms.

angiosperms (*Anthophyta* or *Magnoliophyta*) [14] The flowering plants. Major angiosperm groups include the monocots, eudicots, and magnoliids.

animals (*Animalia* or *Metazoa*) [21] Multicellular heterotrophic eukaryotes. The majority of animals are bilaterians [24]. Other groups of animals include the cnidarians [98], ctenophores [97], placozoans [96], and sponges [22]. The closest living relatives of the animals are the choanoflagellates [92].

annelids (*Annelida*) [105] Segmented worms, including earthworms, leeches, and polychaetes. One of the major groups of lophotrochozoans [26].

anthozoans (*Anthozoa*) One of the major groups of cnidarians [98]. Includes the sea anemones, sea pens, and corals.

anurans (*Anura*) Comprising the frogs and toads, this is the largest group of living amphibians [129]. They are tail-less, with a shortened vertebral column and elongate hind legs modified for jumping. Many species have an aquatic larval form known as a tadpole.

apicomplexans (*Apicomplexa*) [53] Parasitic alveolates [7] characterized by the possession of

an apical complex at some stage in the life cycle.

arachnids (*Arachnida*) Chelicerates [115] with a body divided into two parts: a cephalothorax that bears six pairs of appendages (four pairs of which are usually used as legs) and an abdomen that bears the genital opening. Familiar arachnids include spiders, scorpions, mites and ticks, and harvestmen.

arbuscular mycorrhizal fungi (*Glomeromycota*) [88] A group of fungi [19] that associate with plant roots in a close symbiotic relationship.

archaeans (*Archaea*) [3] Unicellular organisms lacking a nucleus and lacking peptidoglycan in the cell wall. Once grouped with the bacteria, archaeans possess distinctive membrane lipids.

archosaurs (*Archosauria*) [39] A group of reptiles [38] that includes dinosaurs and crocodilians [134]. Most dinosaur groups became extinct at the end of the Cretaceous; birds [133] are the only surviving dinosaurs.

arrow worms (*Chaetognatha*) [107] Small planktonic or benthic predatory marine worms with fins and a pair of hooked, prey-grasping spines on each side of the head.

arthropods (*Arthropoda*) The largest group of ecdysozoans [27]. Arthropods are characterized by a stiff exoskeleton, segmented bodies, and jointed appendages. Includes the chelicerates [115], myriapods [116], crustaceans [117], and hexapods (insects and their relatives) [118].

ascidians (*Ascidacea*) “Sea squirts”; the largest group of urochordates [122]. Also known as tunicates, they are sessile (as adults), marine, saclike filter feeders.

The prokaryotic lineages on this tree are shown in black; the eukaryotic lineages are shown in color. Among the eukaryotes, the microbial lineages are shown in blue. The four eukaryote groups that contain major radiations of multicellular organisms are shown in brown (brown algae), green (Plantae), orange (fungi), and red (animals).

yourBioPortal.com
GO TO The Interactive Tree of Life

– B –

bacteria (*Eubacteria*) [2] Unicellular organisms lacking a nucleus, possessing distinctive ribosomes and initiator tRNA, and generally containing peptidoglycan in the cell wall. Different bacterial groups are distinguished primarily on nucleotide sequence data.

barnacles (*Cirripedia*) Crustaceans [117] that undergo two metamorphoses—first from a feeding planktonic larva to a nonfeeding swimming larva, and then to a sessile adult that forms a “shell” composed of four to eight plates cemented to a hard substrate.

bilaterians (*Bilateria*) [24] Those animal groups characterized by bilateral symmetry and three distinct tissue types (endoderm, ectoderm, and mesoderm). Includes the protostomes [25] and deuterostomes [29].

birds (*Aves*) [133] Feathered, flying (or secondarily flightless) tetrapods [36].

bivalves (*Bivalvia*) Major mollusk [106] group; clams and mussels. Bivalves typically have two similar hinged shells that are each asymmetrical across the midline.

bony vertebrates (*Osteichthyes*) [34] Vertebrates [32] in which the skeleton is usually ossified to form bone. Includes the ray-finned fishes [126], coelacanth [127], lungfishes [128], and tetrapods [36].

brachiopods (*Brachiopoda*) [103] Lophotrochozoans [26] with two similar hinged shells that are each symmetrical across the midline. Superficially resemble bivalve mollusks, except for the shell symmetry.

brittle stars (*Ophiuroidea*) Echinoderms [119] with five long, whip-like arms radiating from a distinct central disk that contains the reproductive and digestive organs.

brown algae (*Phaeophyta*) [49] Multicellular, almost exclusively marine stramenopiles [6] generally containing the pigment fucoxanthin as well as chlorophylls *a* and *c* in their chloroplasts.

bryozoans (*Ectoprocta* or *Bryozoa*) [99] A group of marine and freshwater lophotrochozoans [26] that live in colonies attached to substrata; also known as ectoprocts or moss animals.

– C –

caecilians (*Gymnophiona*) A group of burrowing or aquatic amphibians [129]. They are elongate, legless, with a short tail (or none at all), reduced eyes covered with skin or bone, and a pair of sensory tentacles on the head.

calcareous sponges (*Calcarea*) [95] Filter-feeding marine sponges with spicules composed of calcium carbonate.

cellular slime molds (*Dictyostelida*) Amoebozoans [85] in which individual amoebae aggregate under stress to form a multicellular pseudoplasmodium.

cephalochordates (*Cephalochordata*) [121] A group of weakly swimming, eel-like benthic marine chordates [31]; also called lancelets.

cephalopods (*Cephalopoda*) Active, predatory mollusks [106] in which the molluscan foot has been modified into muscular hydrostatic arms or tentacles. Includes octopuses, squids, and nautilus.

cercozoans (*Cercozoa*) [83] Unicellular eukaryotes [4] that feed by means of threadlike pseudopods. Group together with foraminiferans [82] and radiolarians [84] to comprise the rhizaria [16].

Charales [72] Multicellular green algae with branching, apical growth and plasmodesmata between adjacent cells. The closest living relatives of the land plants [10], they retain the egg in the parent organism.

chelicerates (*Chelicerata*) [115] A major group of arthropods [28] with pointed appendages (chelicerae) used to grasp food (as opposed to the chewing mandibles of most other arthropods). Includes the arachnids, horseshoe crabs, pycnogonids, and extinct sea scorpions.

chimaeras (*Holocephali*) A group of bottom-dwelling, marine, scaleless chondrichthyan fishes [125] with large, permanent, grinding tooth plates (rather than the replaceable teeth found in other chondrichthyans).

chitons (*Polyplocophora*) Flattened, slow-moving mollusks [106] with a dorsal protective calcareous covering made up of eight articulating plates.

chlamydias (*Chlamydiae*) [41] A group of very small Gram-negative bacteria; they live as intracellular parasites of other organisms.

chlorophytes (*Chlorophyta*) [74] The most abundant and diverse group of green algae, including freshwater, marine, and terrestrial forms; some are unicellular, others colonial, and still others multicellular. Chlorophytes use chlorophylls *a* and *c* in their photosynthesis.

choanoflagellates (*Choanozoa*) [92] Unicellular eukaryotes [4] with a single flagellum surrounded by a collar. Most are sessile, some are colonial. The closest living relatives of the animals [21].

chondrichthyans (*Chondrichthyes*) [125] One of the two main groups of jawed vertebrates [33]; includes sharks, rays, and chimaeras. They have cartilaginous skeletons and paired fins.

chordates (*Chordata*) [31] One of the two major groups of deuterostomes [29], characterized by the presence (at some point in development) of a notochord, a hollow dorsal nerve cord, and a post-anal tail. Includes the cephalochordates [121], urochordates [122], and vertebrates [32].

chromalveolates (*Chromalveolata*) [5] A contested group, said to have arisen from a common ancestor with chloroplasts derived from a red alga and supported by some molecular evidence. Major chromalveolate groups include the alveolates [7], stramenopiles [6], and haptophytes [48].

“chytrids” [90] A convenience term used for a paraphyletic group of mostly aquatic, microscopic fungi [19] with flagellated gametes. Some exhibit alternation of generations.

ciliates (*Ciliophora*) [54] Alveolates [7] with numerous cilia and two types of nuclei (micronuclei and macronuclei).

clitellates (*Clitellata*) Annelids [105] with gonads contained in a swelling (called a clitellum) toward the head of the animal. Includes earthworms (oligochaetes) and leeches.

club fungi (*Basidiomycota*) [86] Fungi [19] that, if multicellular, bear the products of meiosis on club-shaped basidia and possess a long-lasting dikaryotic stage. Some are unicellular.

club mosses (*Lycopodiophyta*) [68] Vascular plants [11] characterized by microphylls. See lycophytes.

cnidarians (*Cnidaria*) [98] Aquatic, mostly marine eumetazoans [23] with specialized stinging organelles (nematocysts) used for prey capture and defense, and a blind gastrovascular cavity. The closest living relatives of the ctenophores [97].

coelacanth (*Actinista*) [127] A group of marine sarcopterygians [35] that was diverse from the Middle Devonian to the Cretaceous, but is now known from just two living species. The pectoral and anal fins are on fleshy stalks supported by skeletal elements, so they are also called lobe-finned fishes.

Coleochaetales [73] Multicellular green algae characterized by flattened growth form composed of thin-walled cells. Thought to be the sister-group to the Charales [72] plus land plants [10].

conifers (*Pinophyta* or *Coniferophyta*) [61] Cone-bearing, woody seed plants [12].

copepods (*Copepoda*) Small, abundant crustaceans [117] found in marine, freshwater, or wet terrestrial habitats. They have a single eye, long antennae, and a body shaped like a teardrop.

craniates (*Craniata*) Some biologist exclude the hagfishes [123] from the vertebrates [32], and use the term craniates to refer to the two groups combined.

crenarchaeotes (*Crenarchaeota*) [46] A major and diverse group of archaeans [3], defined on the basis of rRNA base sequences. Many are extremophiles (inhabit extreme environments), but the group may also be the most abundant archaeans in the marine environment.

crinoids (*Crinoidea*) Echinoderms [119] with a mouth surrounded by feeding arms, and a U-shaped gut with the mouth next to the anus. They attach to the substratum by a stalk or are free-swimming. Crinoids were abundant in the middle and late Paleozoic, but only a few hundred species have survived to the present. Includes the sea lilies and feather stars.

crocodilians (*Crocodylia*) [134] A group of large, predatory, aquatic archosaurs [39]. The closest living relatives of birds [133]. Includes alligators, caimans, crocodiles, and gharials.

crustaceans (*Crustacea*) [117] Major group of marine, freshwater, and terrestrial arthropods [28] with a head, thorax, and abdomen (although the head and thorax may be fused), covered with a thick exoskeleton, and with two-part appendages. Crustaceans undergo metamorphosis from a nauplius larva. Includes decapods, isopods, krill, barnacles, amphipods, copepods, and ostracods.

ctenophores (*Ctenophora*) [97] Radially symmetrical, diploblastic marine animals [21], with a complete gut and eight rows of fused plates of cilia (called ctenes).

cyanobacteria (*Cyanobacteria*) [43] A group of unicellular, colonial, or filamentous bacteria that conduct photosynthesis using chlorophyll *a*.

cycads (*Cycadophyta*) [64] Palmlike gymnosperms with large, compound leaves.

cyclostomes (*Cyclostomata*) This term refers to the possibly monophyletic group of lampreys [124] and hagfishes [123]. Molecular data support this group, but morphological data suggest that lampreys are more closely related to jawed vertebrates [33] than to hagfishes.

- D -

decapods (*Decapoda*) A group of marine, freshwater, and semiterrestrial crustaceans [117] in which five of the eight pairs of thoracic appendages function as legs (the other three pairs, called maxillipeds, function as mouthparts). Includes crabs, lobsters, crayfishes, and shrimps.

demosponges (*Demospongiae*) [94] The largest of the three groups of sponges [22], accounting for 90 percent of all sponge species. Demosponges have spicules made of silica, spongin fiber (a protein), or both.

deuterostomes (*Deuterostomia*) [29] One of the two major groups of bilaterians [24], in which the mouth forms at the opposite end of the embryo from the blastopore in early development (contrast with protostomes). Includes the ambulacrarians [30] and chordates [31].

diatoms (*Bacillariophyta*) [50] Unicellular, photosynthetic stramenopiles [6] with glassy cell walls in two parts.

dikaryotic fungi (*Dikarya*) [20] A group of fungi [19] in which two genetically different haploid nuclei coexist and divide within the same hypha; includes club fungi [86] and sac fungi [87].

dinoflagellates (*Dinoflagellata*) [52] A group of alveolates [7] usually possessing two flagella, one in an equatorial groove and the other in a longitudinal groove; many are photosynthetic.

diplomonads (*Diplomonadida*) [81] A group of eukaryotes [4] lacking mitochondria; most have two nuclei, each with four associated flagella.

- E -

ecdysozoans (*Ecdysozoa*) [27] One of the two major groups of protostomes [25], characterized by periodic molting of their exoskeletons. Nematodes [112] and arthropods [28] are the largest ecdysozoan groups.

echinoderms (*Echinodermata*) [119] A major group of marine deuterostomes [29] with five-fold radial symmetry (at some stage of life) and an endoskeleton made of calcified plates and spines. Includes sea stars, crinoids, sea urchins, sea cucumbers, and brittle stars.

elasmobranchs (*Elasmobranchii*) The largest group of chondrichthyan fishes [125]. Includes sharks, skates, and rays. In contrast to the other group of living chondrichthyans (the chimaeras), they have replaceable teeth.

embryophytes See land plants [10].

eudicots (*Eudicotyledones*) [55] A group of angiosperms [14] with pollen grains possessing three openings. Typically with two cotyledons, net-veined leaves, taproots, and floral organs typically in multiples of four or five.

euglenids (*Euglenida*) [78] Flagellate excavates characterized by a pellicle composed of spiraling strips of protein under the plasma membrane; the mitochondria have disk-shaped cristae. Some are photosynthetic.

eukaryotes (*Eukarya*) [4] Organisms made up of one or more complex cells in which the genetic material is contained in nuclei. Contrast with archaeans [3] and bacteria [2].

eumetazoans (*Eumetazoa*) [23] Those animals [21] characterized by body symmetry, a gut, a nervous system, specialized types of cell junctions, and well-organized tissues in distinct cell layers (although there have been secondary losses of some of these characteristics in some eumetazoans).

euphyllophytes (*Euphyllophyta*) The group of vascular plants [11] that is sister to the lycophytes [68] and which includes all plants with megaphylls.

euryarchaeotes (*Euryarchaeota*) [47] A major group of archaeans [3], diagnosed on the basis of rRNA sequences. Includes many methanogens, extreme halophiles, and thermophiles.

eutherians (*Eutheria*) A group of viviparous mammals [130], eutherians are well developed at birth (contrast to prototherians and marsupials, the other two groups of mammals). Most familiar mammals outside the Australian and South American regions are eutherians (see Table 33.1).

excavates (*Excavata*) [15] Diverse group of unicellular, flagellate eukaryotes, many of which possess a feeding groove; some lack mitochondria.

- F -

"ferns" Vascular plants [11] usually possessing large, frondlike leaves that unfold from a "fiddlehead." Not a monophyletic group, although most fern species are encompassed in a monophyletic clade, the leptosporangiate ferns [65].

flatworms (*Platyhelminthes*) [100] A group of dorsoventrally flattened and generally elongate soft-bodied lophotrochozoans [26]. May be free-living or parasitic, found in marine, freshwater, or damp terrestrial environments. Major flatworm groups include the tapeworms, flukes, monogeneans, and turbellarians.

flowering plants See angiosperms [14].

flukes (*Trematoda*) A group of wormlike parasitic flatworms [100] with complex life cycles that involve several different host species. May be paraphyletic with respect to tapeworms.

foraminiferans (*Foraminifera*) [82] Amoeboid organisms with fine, branched pseudopods that form a food-trapping net. Most produce external shells of calcium carbonate.

fungi (*Fungi*) [19] Eukaryotic heterotrophs with absorptive nutrition based on extracellular digestion; cell walls contain chitin. Major fungal groups include the microsporidia [91], "chytrids" [90], "zygospore fungi" [89], arbuscular mycorrhizal fungi [88], sac fungi [87], and club fungi [86].

- G -

gastropods (*Gastropoda*) The largest group of mollusks [106]. Gastropods possess a well-defined head with two or four sensory tentacles (often terminating in eyes) and a ventral foot. Most species have a single coiled or spiraled shell. Common in marine, freshwater, and terrestrial environments.

ginkgo (*Ginkgophyta*) [63] A gymnosperm [13] group with only one living species. The ginkgo seed is surrounded by a fleshy tissue not derived from an ovary wall and hence not a fruit.

glass sponges (*Hexactinellida*) [93] Sponges [22] with a skeleton composed of four- and/or six-pointed spicules made of silica.

glaucophytes (*Glaucophyta*) [76] Unicellular freshwater algae with chloroplasts containing traces of peptidoglycan, the characteristic cell wall material of bacteria.

gnathostomes (*Gnathostomata*) See jawed vertebrates [33].

gnetophytes (*Gnetophyta*) [62] A gymnosperm [13] group with three very different lineages; all have wood with vessels, unlike other gymnosperms.

green plants (*Viridiplantae*) [9] Organisms with chlorophylls *a* and *b*, cellulose-containing cell walls, starch as a carbohydrate storage product, and chloroplasts surrounded by two membranes.

gymnosperms (*Gymnospermae*) [13] Seed plants [12] with seeds "naked" (i.e., not enclosed in carpels). Probably monophyletic, but status still in doubt. Includes the conifers [61], gnetophytes [62], ginkgo [63], and cycads [64].

- H -

hagfishes (*Myxini*) [123] Elongate, slimy-skinned vertebrates [32] with three small accessory hearts, a partial cranium, and no stomach or paired fins. See also craniata; cyclostomes.

haptophytes (*Haptophyta*) [48] Unicellular, photosynthetic chromalveolates [5] with two slightly unequal, smooth flagella. Abundant as phytoplankton, some form marine algal blooms.

hemichordates (*Hemichordata*) [120] One of the two primary groups of ambulacrarians [30]; marine wormlike organisms with a three-part body plan.

heteroloboseans (*Heterolobosea*) [79] Colorless excavates [15] that can transform among amoeboid, flagellate, and encysted stages.

hexapods (*Hexapoda*) [118] Major group of arthropods [28] characterized by a reduction (from the ancestral arthropod condition) to six walking appendages, and the consolidation of three body segments to form a thorax. Includes insects and their relatives (see Table 32.2).

high-GC Gram-positives (*Actinobacteria*) [42] Gram-positive bacteria with a relatively high (G+C)/(A+T) ratio of their DNA, with a filamentous growth habit.

hornworts (*Anthoceroophyta*) [69] Nonvascular plants with sporophytes that grow from the base. Cells contain a single large, platelike chloroplast.

horsehair worms (*Nematomorpha*) [111] A group of very thin, elongate, wormlike freshwater ecdysozoans [27]. Largely nonfeeding as adults, they are parasites of insects and crayfish as larvae.

horseshoe crabs (*Xiphosura*) Marine chelicerates [115] with a large outer shell in three parts: a carapace, an abdomen, and a tail-like telson. There are only five living species, but many additional species are known from fossils.

horsetails (*Sphenophyta* or *Equisetophyta*) [66] Vascular plants [11] with reduced megaphylls in whorls.

hydrozoans (*Hydrozoa*) A group of cnidarians [98]. Most species go through both polyp and mesoda stages, although one stage or the other is eliminated in some species.

- I -

insects (*Insecta*) The largest group within the hexapods [118]. Insects are characterized by exposed mouthparts and one pair of antennae containing a sensory receptor called a Johnston's organ. Most have two pairs of wings as adults. There are more described species of insects than all other groups of life [1] combined, and many species remain to be discovered. The major insect groups are described in Table 32.2.

"invertebrates" A convenience term that encompasses any animal [21] that is not a vertebrate [32].

isopods (*Isopoda*) Crustaceans [117] characterized by a compact head, unstalked compound eyes, and mouthparts consisting of four pairs of appendages. Isopods are abundant and widespread in salt, fresh, and brackish water, although some species (the sow bugs) are terrestrial.

- J -

jawed vertebrates (*Gnathostomata*) [33] A major group of vertebrates [32] with jawed mouths. Includes chondrichthyans [125], ray-finned fishes [126], and sarcopterygians [35].

- K -

kinetoplastids (*Kinetoplastida*) [77] Unicellular, flagellate organisms characterized by the presence in their single mitochondrion of a kinetoplast (a structure containing multiple, circular DNA molecules).

kinorhynchs (*Kinorhyncha*) [109] Small (<1 mm) marine ecdysozoans [27] with bodies in 13 segments and a retractable proboscis.

korarchaeotes (*Korarchaeota*) A group of archaeans [3] known only by evidence from nucleic acids derived from hot springs. Its phylogenetic relationships within the Archaea are unknown.

krill (*Euphausiacea*) A group of shrimplike marine crustaceans [117] that are important components of the zooplankton.

- L -

lampreys (*Petromyzontiformes*) [124] Elongate, eel-like vertebrates [32] that often have rasping and sucking disks for mouths.

lancelets (*Cephalochordata*) See cephalochordates [121].

land plants (*Embryophyta*) [10] Plants with embryos that develop within protective structures; also called embryophytes. Sporophytes and gametophytes are multicellular. Land plants possess a cuticle. Major groups are the liverworts [71], mosses [70], hornworts [69], and vascular plants [11].

larvaceans (*Larvacea*) Solitary, planktonic urochordates [122] that retain both notochords and nerve cords throughout their lives.

lepidosaurs (*Lepidosauria*) [132] Reptiles [38] with overlapping scales. Includes tuataras and

squamates (lizards, snakes, and amphisbaenians).

leptosporangiate ferns (*Pteridopsida* or *Polypodiopsida*) [65] Vascular plants [11] usually possessing large, frondlike leaves that unfold from a "fiddlehead," and possessing thin-walled sporangia.

life (*Life*) [1] The monophyletic group that includes all known living organisms. Characterized by a nucleic-acid based genetic system (DNA or RNA), metabolism, and cellular structure. Some parasitic forms, such as viruses, have secondarily lost some of these features and rely on the cellular environment of their host.

liverworts (*Hepatophyta*) [71] Nonvascular plants lacking stomata; stalk of sporophyte elongates along its entire length.

loboseans (*Lobosea*) A group of unicellular amoebozoans [85]; includes the most familiar amoebas (e.g., *Amoeba proteus*).

"lophophorates" Not a monophyletic group. A convenience term used to describe several groups of lophotrochozoans [26] that have a feeding structure called a lophophore (a circular or U-shaped ridge around the mouth that bears one or two rows of ciliated, hollow tentacles).

lophotrochozoans (*Lophotrochozoa*) [26] One of the two main groups of protostomes [25]. This group is morphologically diverse, and is supported primarily on information from gene sequences. Includes bryozoans [99], flatworms [100], rotifers [101], ribbon worms [102], brachiopods [103], phoronids [104], annelids [105], and mollusks [106].

loriciferans (*Loricifera*) [110] Small (<1 mm) ecdysozoans [27] with bodies in four parts, covered with six plates.

low-GC Gram-positives (*Firmicutes*) [44] A diverse group of bacteria [2] with a relatively low (G+C)/(A+T) ratio of their DNA, often but not always Gram-positive, some producing endospores.

lungfishes (*Dipnoi*) [128] A group of aquatic sarcopterygians [35] that are the closest living relatives of the tetrapods [36]. They have a modified swim bladder used to absorb oxygen from air, so some species can survive the temporary drying of their habitat.

lycophytes (*Lycopodiophyta*) [68] Vascular plants [11] characterized by microphylls; includes club mosses, spike mosses, and quillworts.

- M -

magnoliids (*Magnoliidae*) [57] A major group of angiosperms [14] possessing two cotyledons and pollen grains with a single opening. The group is defined primarily by nucleotide sequence data; it is more closely related to the eudicots and monocots than to three other small angiosperm groups.

mammals (*Mammalia*) [130] A group of tetrapods [36] with hair covering all or part of their skin; females produce milk to feed their developing young. Includes the prototherians, marsupials, and eutherians.

marsupials (*Marsupialia*) Mammals [130] in which the female typically has a marsupium (a pouch for rearing young, which are born at an

extremely early stage in development). Includes such familiar mammals as opossums, koalas, and kangaroos.

metazoans (*Metazoa*) See animals [21].

microbial eukaryotes See "protists."

microsporidia (*Microsporidia*) [91] A group of parasitic unicellular fungi [19] that lack mitochondria and have walls that contain chitin.

mollusks (*Mollusca*) [106] One of the major groups of lophotrochozoans [26], mollusks have bodies composed of a foot, a mantle (which often secretes a hard, calcareous shell), and a visceral mass. Includes monoplacophorans, chitons, bivalves, gastropods, and cephalopods.

monilophytes (*Monilophyta*) A group of vascular plants [11], sister to the seed plants [12], characterized by overtopping and possession of megaphylls; includes the ferns [65], horsetails [66], and whisk ferns [67].

monocots (*Monocotyledones*) [56] Angiosperms [14] characterized by possession of a single cotyledon, usually parallel leaf veins, a fibrous root system, pollen grains with a single opening, and floral organs usually in multiples of three.

monogeneans (*Monogenea*) A group of ectoparasitic flatworms [100].

monoplacophorans (*Monoplacophora*) Mollusks [106] with segmented body parts and a single, thin, flat, rounded, bilateral shell.

mosses (*Bryophyta*) [70] Nonvascular plants with true stomata and erect, "leafy" gametophytes; sporophytes elongate by apical cell division.

moss animals See bryozoans [99].

myriapods (*Myriapoda*) [116] Arthropods [28] characterized by an elongate, segmented trunk with many legs. Includes centipedes and millipedes.

- N -

nanoarchaeotes (*Nanoarchaeota*) A group of extremely small, thermophilic archaeans [3] with a much-reduced genome. The only described example can survive only when attached to a host organism.

nematodes (*Nematoda*) [112] A very large group of elongate, unsegmented ecdysozoans [27] with thick, multilayer cuticles. They are among the most abundant and diverse animals, although most species have not yet been described. Include free-living predators and scavengers, as well as parasites of most species of land plants [10] and animals [21].

neognaths (*Neognathae*) The main group of birds [133], including all living species except the ratites (ostrich, emu, rheas, kiwis, cassowaries) and tinamous. See palaeognaths.

- O -

oligochaetes (*Oligochaeta*) An annelid [105] group whose members lack parapodia, eyes, and anterior tentacles, and have few setae. Earthworms are the most familiar oligochaetes.

onychophorans (*Onychophora*) [114] Elongate, segmented ecdysozoans [27] with many pairs of soft, unjointed, claw-bearing legs. Also known as velvet worms.

oomycetes (*Oomycota*) [51] Water molds and relatives; absorptive heterotrophs with nutrient-absorbing, filamentous hyphae.

opisthokonts (*Opisthokonta*) [18] A group of unikonts [17] in which the flagellum on motile cells, if present, is posterior. The opisthokonts include the fungi [19], animals [21], and choanoflagellates [92].

ostracods (*Ostracoda*) Marine and freshwater crustaceans [117] that are laterally compressed and protected by two clamlike calcareous or chitinous shells.

– P –

palaeognaths (*Palaeognathae*) A group of secondarily flightless or weakly flying birds [133]. Includes the flightless ratites (ostrich, emu, rheas, kiwis, cassowaries) and the weakly flying tinamous.

parabasalids (*Parabasalia*) [80] A group of unicellular eukaryotes [4] that lack mitochondria; they possess flagella in clusters near the anterior of the cell.

phoronids (*Phoronida*) [104] A small group of sessile, wormlike marine lophotrochozoans [26] that secrete chitinous tubes and feed using a lophophore.

placoderms (*Placodermi*) An extinct group of jawed vertebrates [33] that lacked teeth. Placoderms were the dominant predators in Devonian oceans.

placozoans (*Placozoa*) [96] A poorly known group of structurally simple, asymmetrical, flattened, transparent animals found in coastal marine tropical and subtropical seas. Most evidence suggests that placozoans are the sister-group of eumetazoans [23].

Plantae [8] The most broadly defined plant group. In most parts of this book, we use the word “plant” as synonymous with “land plant” [10], a more restrictive definition.

plasmodial slime molds (*Myxogastriida*) Amoebozoans [85] that in their feeding stage consist of a coenocyte called a plasmodium.

pogonophorans (*Pogonophora*) Deep-sea annelids [105] that lack a mouth or digestive tract; they feed by taking up dissolved organic matter, facilitated by endosymbiotic bacteria in a specialized organ (the trophosome).

polychaetes (*Polychaeta*) A group of mostly marine annelids [105] with one or more pairs of eyes and one or more pairs of feeding tentacles; parapodia and setae extend from most body segments. May be paraphyletic with respect to the clitellates.

priapulids (*Priapulida*) [108] A small group of cylindrical, unsegmented, wormlike marine ecdysozoans [27] that takes its name from its phallic appearance.

“progymnosperms” Paraphyletic group of extinct vascular plants [11] that flourished from the Devonian through the Mississippian periods. The first truly woody plants, and the first with vascular cambium that produced both secondary xylem and secondary phloem, they reproduced by spores rather than by seeds.

“prokaryotes” Not a monophyletic group; as commonly used, includes the bacteria [2] and archaeans [3]. A term of convenience encompassing all cellular organisms that are not eukaryotes.

proteobacteria (*Proteobacteria*) [45] A large and extremely diverse group of Gram-negative bacteria that includes many pathogens, nitrogen fixers, and photosynthesizers. Includes the alpha, beta, gamma, delta, and epsilon proteobacteria.

“protists” This term of convenience does not describe a monophyletic group but is used to encompass a large number of distinct and distantly related groups of eukaryotes, many but far from all of which are microbial and unicellular. Essentially a “catch-all” term for any eukaryote group not contained within the land plants [10], fungi [19], or animals [21].

protostomes (*Protostomia*) [25] One of the two major groups of bilaterians [24]. In protostomes, the mouth typically forms from the blastopore (if present) in early development (contrast with deuterostomes). The major protostome groups are the lophotrochozoans [26] and ecdysozoans [27].

prototherians (*Prototheria*) A mostly extinct group of mammals [130], common during the Cretaceous and early Cenozoic. The five living species—the echidnas and the duck-billed platypus—are the only extant egg-laying mammals.

pterobranchs (*Pterobranchia*) A small group of sedentary marine hemichordates [120] that live in tubes secreted by the proboscis. They have one to nine pairs of arms, each bearing long tentacles that capture prey and function in gas exchange.

pycnogonids (*Pycnogonida*) Treated in this book as a group of chelicerates [115], but sometimes considered an independent group of arthropods [28]. Pycnogonids have reduced bodies and very long, slender legs. Also called sea spiders.

– R –

radiolarians (*Radiolaria*) [84] Amoeboid organisms with needlelike pseudopods supported by microtubules. Most have glassy internal skeletons.

ray-finned fishes (*Actinopterygii*) [126] A highly diverse group of freshwater and marine bony vertebrates [34]. They have reduced swim bladders that often function as hydrostatic organs and fins supported by soft rays (lepidotrichia). Includes most familiar fishes.

red algae (*Rhodophyta*) [75] Mostly multicellular, marine and freshwater algae characterized by the presence of phycoerythrin in their chloroplasts.

reptiles (*Reptilia*) [38] One of the two major groups of extant amniotes [37], supported on the basis of similar skull structure and gene sequences. The term “reptiles” traditionally excluded the birds [133], but the resulting group is then clearly paraphyletic. As used in this book, the reptiles include turtles [131], lepidosaurs [132], birds [133], and crocodilians [134].

rhizaria (*Rhizaria*) [16] Mostly amoeboid unicellular eukaryotes with pseudopods, many with external or internal shells. Includes the foraminiferans [82], cercozoans [83], and radiolarians [84].

rhyniophytes (*Rhyniophyta*) A group of early vascular plants [11] that appeared in the Silurian and became extinct in the Devonian. Pos-

sessed dichotomously branching stems with terminal sporangia but no true leaves or roots.

ribbon worms (*Nemertea*) [102] A group of unsegmented lophotrochozoans [26] with an eversible proboscis used to capture prey. Mostly marine, but some species live in fresh water or on land.

rotifers (*Rotifera*) [101] Tiny (<0.5 mm) lophotrochozoans [26] with a pseudocoelomic body cavity that functions as a hydrostatic organ and a ciliated feeding organ called the corona that surrounds the head. They live in freshwater and wet terrestrial habitats.

roundworms (*Nematoda*) [112] See nematodes.

– S –

sac fungi (*Ascomycota*) [87] Fungi that bear the products of meiosis within sacs (asci) if the organism is multicellular. Some are unicellular.

salamanders (*Caudata*) A group of amphibians [129] with distinct tails in both larvae and adults and limbs set at right angles to the body.

salps See thaliaceans.

sarcopterygians (*Sarcopterygii*) [35] One of the two major groups of bony vertebrates [34], characterized by jointed appendages (paired fins or limbs).

scyphozoans (*Scyphozoa*) Marine cnidarians [98] in which the medusa stage dominates the life cycle. Commonly known as jellyfish.

sea cucumbers (*Holothuroidea*) Echinoderms [119] with an elongate, cucumber-shaped body and leathery skin. They are scavengers on the ocean floor.

sea spiders See pycnogonids.

sea squirts See ascidians.

sea stars (*Asteroidea*) Echinoderms [119] with five (or more) fleshy “arms” radiating from an indistinct central disk. Also called starfishes.

sea urchins (*Echinoidea*) Echinoderms [119] with a test (shell) that is covered in spines. Most are globular in shape, although some groups (such as the sand dollars) are flattened.

“seed ferns” A paraphyletic group of loosely related, extinct seed plants that flourished in the Devonian and Carboniferous. Characterized by large, frondlike leaves that bore seeds.

seed plants (*Spermatophyta*) [12] Heterosporous vascular plants [11] that produce seeds; most produce wood; branching is axillary (not dichotomous). The major seed plant groups are gymnosperms [13] and angiosperms [14].

sow bugs See isopods.

spirochetes (*Spirochaetes*) [40] Motile, Gram-negative bacteria with a helically coiled structure and characterized by axial filaments.

sponges (*Porifera*) [22] A group of relatively asymmetric, filter-feeding animals that lack a gut or nervous system and generally lack differentiated tissues. Includes glass sponges [93], demosponges [94], and calcareous sponges [95].

springtails (*Collembola*) Wingless hexapods [118] with springing structures on the third and fourth segments of their bodies. Springtails are extremely abundant in some environments (especially in soil, leaf litter, and vegetation).

squamates (*Squamata*) The major group of lepidosaurs [132], characterized by the posses-

sion of movable quadrate bones (which allow the upper jaw to move independently of the rest of the skull) and hemipenes (a paired set of eversible penises, or penes) in males. Includes the lizards (a paraphyletic group), snakes, and amphisbaenians.

star anise (*Austrobaileyales*) [58] A group of woody angiosperms [14] thought to be the sister-group of the clade of flowering plants that includes eudicots [55], monocots [56], and magnoliids [57].

starfish (*Asteroidea*) See sea stars.

stramenopiles (*Heterokonta* or *Stramenopila*) [6] Organisms having, at some stage in their life cycle, two unequal flagella, the longer possessing rows of tubular hairs. Chloroplasts, when present, surrounded by four membranes. Major stramenopile groups include the brown algae [49], diatoms [50], and oomycetes [51].

- T -

tapeworms (*Cestoda*) Parasitic flatworms [100] that live in the digestive tracts of vertebrates as adults, and usually in various other species of animals as juveniles.

tardigrades (*Tardigrada*) [113] Small (< 0.5 mm) ecdysozoans [27] with fleshy, unjointed legs and no circulatory or gas exchange organs. They live in marine sands, in temporary freshwater pools, and on the water films of plants. Also called water bears.

tetrapods (*Tetrapoda*) [36] The major group of sarcopterygians [35]; includes the amphibians [129] and the amniotes [37]. Named for the presence of four jointed limbs (although limbs have been secondarily reduced or lost completely in several tetrapod groups).

thaliaceans (*Thaliacea*) A group of solitary or colonial planktonic marine urochordates [122]. Also called salps.

therians (*Theria*) Mammals [130] characterized by viviparity (live birth). Includes eutherians and marsupials.

theropods (*Theropoda*) Archosaurs [39] with bipedal stance, hollow bones, a furcula (“wish-bone”), elongated metatarsals with three-fingered feet, and a pelvis that points backwards. Includes many well-known extinct dinosaurs (such as *Tyrannosaurus rex*), as well as the living birds [133].

tracheophytes See vascular plants [11].

trilobites (*Trilobita*) An extinct group of arthropods [28] related to the chelicerates [115]. Trilobites flourished from the Cambrian through the Permian.

tuataras (*Rhynchocephalia*) A group of lepidosaurs [132] known mostly from fossils; there are just two living tuatara species. The quadrate bone of the upper jaw is fixed firmly to the skull. Sister group of the squamates.

tunicates See ascidians.

turbellarians (*Turbellaria*) A group of free-living, generally carnivorous flatworms [100]. Their monophyly is questionable.

turtles (*Testudines*) [131] A group of reptiles [38] with a bony carapace (upper shell) and plastron (lower shell) that encase the body.

- U -

unikonts (*Unikonta*) [17] A group of eukaryotes [4] whose motile cells possess a single flagellum. Major unikont groups include the amoebozoans [85], fungi [19], and animals [21].

urochordates (*Urochordata*) [122] A group of chordates [31] that are mostly saclike filter feeders as adults, with motile larvae stages that resemble a tadpole.

- V -

vascular plants (*Tracheophyta*) [11] Plants with xylem and phloem. Major groups include the lycophytes [68] and euphyllophytes.

vertebrates (*Vertebrata*) [32] The largest group of chordates [31], characterized by a rigid endoskeleton supported by the vertebral column and an anterior skull encasing a brain. Includes hagfishes [123], lampreys [124], and the jawed vertebrates [33], although some biologists exclude the hagfishes from this group. See also craniates.

- W -

water bears See tardigrades.

water lilies (*Nymphaeaceae*) [59] A group of aquatic, freshwater angiosperms [14] that are rooted in soil in shallow water, with round floating leaves and flowers that extend above the water’s surface. They are the sister-group to most of the remaining flowering plants, with the exception of the genus *Amborella* [60].

whisk ferns (*Psilotophyta*) [67] Vascular plants [11] lacking leaves and roots.

- Y -

“yeasts” A convenience term for several distantly related groups of unicellular fungi [19].

- Z -

“zygospore fungi” (*Zygomycota*, if monophyletic) [89] A convenience term for a probably paraphyletic group of fungi [19] in which hyphae of differing mating types conjugate to form a zygosporangium.

Appendix B: Some Measurements Used in Biology

MEASURES OF	UNIT	EQUIVALENTS	METRIC → ENGLISH CONVERSION
Length	meter (m)	base unit	1 m = 39.37 inches = 3.28 feet
	kilometer (km)	1 km = 1000 (10^3) m	1 km = 0.62 miles
	centimeter (cm)	1 cm = 0.01 (10^{-2}) m	1 cm = 0.39 inches
	millimeter (mm)	1 mm = 0.1 cm = 10^{-3} m	1 mm = 0.039 inches
	micrometer (μm)	1 μm = 0.001 mm = 10^{-6} m	
	nanometer (nm)	1 nm = 0.001 μm = 10^{-9} m	
Area	square meter (m ²)	base unit	1 m ² = 1.196 square yards
	hectare (ha)	1 ha = 10,000 m ²	1 ha = 2.47 acres
Volume	liter (L)	base unit	1 L = 1.06 quarts
	milliliter (mL)	1 mL = 0.001 L = 10^{-3} L	1 mL = 0.034 fluid ounces
	microliter (μL)	1 μL = 0.001 mL = 10^{-6} L	
Mass	gram (g)	base unit	1 g = 0.035 ounces
	kilogram (kg)	1 kg = 1000 g	1 kg = 2.20 pounds
	metric ton (mt)	1 mt = 1000 kg	1 mt = 2,200 pounds = 1.10 ton
	milligram (mg)	1 mg = 0.001 g = 10^{-3} g	
	microgram (μg)	1 μg = 0.001 mg = 10^{-6} g	
Temperature	degree Celsius (°C)	base unit	°C = (°F – 32)/1.8 0°C = 32°F (water freezes) 100°C = 212°F (water boils) 20°C = 68°F (“room temperature”) 37°C = 98.6°F (human internal body temperature)
	Kelvin (K)*	K = °C + 273	0 K = –460°F
Energy	joule (J)		1 J ≈ 0.24 calorie = 0.00024 kilocalorie [†]

*0 K (–273°C) is “absolute zero,” a temperature at which molecular oscillations approach 0—that is, the point at which motion all but stops.
[†]A *calorie* is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. The *kilocalorie*, or nutritionist’s calorie, is what we commonly think of as a calorie in terms of food.

*Answers to Chapter 12 Genetics Problems

1. $BB \times bb; bb \times bb; Bb \times bb; Bb \times Bb$
2. $1/32$
- 3a. Autosomal dominant
- 3b. $1/4$
- 4a. Males (XY) contain only one allele and will show only one color, black (X^BY) or yellow (X^bY). Females can be heterozygous (X^BX^b).
- 4b. X^bY , yellow
5. The body color (G/g) and wing size (A/a) genes are linked; eye color (R/r) is unlinked to the other two genes. The map distance is 18.5 units.
6. Yellow, blue, and white in a 1:2:1 ratio
7. F_1 all wild-type, $PpSsww$; F_2 will have phenotypes in the ratio 9:3:3:1. See Figure 12.7 (p. 244) for analogous genotypes.
- 8a. Ratio of phenotypes in F_2 is 3:1 (double dominant to double recessive).

- 8b. The F_1 are $PpByby$; they produce just two kinds of gametes (Pby and pBy). Combine them carefully and see the 1:2:1 phenotypic ratio fall out in the F_2 .
- 8c. Pink-blistery
- 8d. See Figures 11.17 and 11.19 (pp. 224–226). Crossing over took place in the F_1 generation.
9. $Rraa$ and $RrAa$
- 10a. $w^+ > w^e > w$
- 10b. Parents are $w^e w$ and $w^+ Y$. Progeny are $w^+ w^e$, $w^+ w$, $w^e Y$, and $w Y$.
- 11a. BX^a , BY , bX^a , bY
- 11b. Mother $bbX^A X^a$, father $BbX^a Y$, son $BbX^a Y$, daughter $bbX^a X^a$
12. 75 percent
13. Because the gene is carried on mitochondrial DNA, it is passed through the mother only. Thus if the woman does not have the disease but her husband does, their child will not be affected. On the other hand, if the woman has the disease but her husband does not, their child will have the disease.

Glossary

- A -

abiotic (a' bye ah tick) [Gk. *a*: not + *bios*: life] Nonliving. (Contrast with biotic.)

abscisic acid (ABA) (ab sighs' ik) A plant growth substance with growth-inhibiting action. Causes stomata to close; involved in a plant's response to salt and drought stress.

abscission (ab sizh' un) [L. *abscissio*: break off] The process by which leaves, petals, and fruits separate from a plant.

absorption (1) Of light: complete retention, without reflection or transmission. (2) Of water or other molecules: soaking up (taking in through pores or by diffusion).

absorption spectrum A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

absorptive heterotroph An organism (usually a fungus) that obtains its food by secreting digestive enzymes into the environment to break down large food molecules, then absorbing the breakdown products.

abyssal plain (uh biss' ul) [Gk. *abyssos*: bottomless] The deep ocean floor.

accessory pigments Pigments that absorb light and transfer energy to chlorophylls for photosynthesis.

acetylcholine (ACh) A neurotransmitter that carries information across vertebrate neuromuscular junctions and some other synapses. It is then broken down by the enzyme acetylcholinesterase (AChE).

acetyl coenzyme A (acetyl CoA) A compound that reacts with oxaloacetate to produce citrate at the beginning of the citric acid cycle; a key metabolic intermediate in the formation of many compounds.

acid [L. *acidus*: sharp, sour] A substance that can release a proton in solution. (Contrast with base.)

acid growth hypothesis The hypothesis that auxin increases proton pumping, thereby lowering the pH of the cell wall and activating enzymes that loosen polysaccharides. Proposed to explain auxin-induced cell expansion in plants.

acid precipitation Precipitation that has a lower pH than normal as a result of acid-forming precursor molecules introduced into the atmosphere by human activities.

acidic Having a pH of less than 7.0 (a hydrogen ion concentration greater than 10^{-7} molar). (Contrast with basic.)

acoelomate An animal that does not have a coelom.

acrosome (a' krow soam) [Gk. *akros*: highest + *soma*: body] The structure at the forward tip of an animal sperm which is the first to fuse with the egg membrane and enter the egg cell.

ACTH See corticotropin.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle.

action potential An impulse in a neuron taking the form of a wave of depolarization or hyperpolarization.

action spectrum A graph of a biological process versus light wavelength; shows which wavelengths are involved in the process.

activation energy (E_a) The energy barrier that blocks the tendency for a chemical reaction to occur.

active site The region on the surface of an enzyme or ribozyme where the substrate binds, and where catalysis occurs.

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See also primary active transport, secondary active transport; contrast with facilitated diffusion, passive transport.)

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

adaptive radiation An evolutionary radiation that results in an array of related species that live in a variety of environments and differ in the characteristics they use to exploit those environments.

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

adenosine triphosphate See ATP.

adrenal gland (a dree' nal) [L. *ad*: toward + *renes*: kidneys] An endocrine gland located near the kidneys of vertebrates, consisting of two glandular parts, the cortex and medulla.

adrenaline See epinephrine.

adrenocorticotrophic hormone See corticotropin.

adsorption Binding of a gas or a solute to the surface of a solid.

adventitious roots (ad ven ti' shus) [L. *adventitiuus*: arriving from outside] Roots originating from the stem at ground level or below; typical of the fibrous root system of monocots.

aerenchyma In plants, parenchymal tissue containing air spaces.

aerobic (air oh' bic) [Gk. *aer*: air + *bios*: life] In the presence of oxygen; requiring oxygen. (Contrast with anaerobic.)

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in a neuron that carries impulses to the central nervous system (afferent neuron), or a blood vessel that carries blood to a structure. (Contrast with efferent.)

age structure The distribution of the individuals in a population across all age groups.

AIDS Acquired immune deficiency syndrome, a condition caused by human immunodeficiency virus (HIV) in which the body's T-helper cells are

reduced, leaving the victim subject to opportunistic diseases.

air sacs Structures in the respiratory system of birds that receive inhaled air; they keep fresh air flowing unidirectionally through the lungs, but are not themselves gas exchange surfaces.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

aleurone layer In some seeds, a tissue that lies beneath the seed coat and surrounds the endosperm. Secretes digestive enzymes that break down macromolecules stored in the endosperm.

allantoic membrane In animal development, an outgrowth of extraembryonic endoderm plus adjacent mesoderm that forms the allantois, a saclike structure that stores metabolic wastes produced by the embryo.

allantois (al lun twah') [Gk. *allant*: sausage] An extraembryonic membrane enclosing a sausage-shaped sac that stores the embryo's nitrogenous wastes.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

allele frequency The relative proportion of a particular allele in a specific population.

allergic reaction [Ger. *allergie*: altered] An overreaction of the immune system to amounts of an antigen that do not affect most people; often involves IgE antibodies.

allometric growth A pattern of growth in which some parts of the body of an organism grow faster than others, resulting in a change in body proportions as the organism grows.

allopatric speciation (al' lo pat' rick) [Gk. *allos*: other + *patria*: homeland] The formation of two species from one when reproductive isolation occurs because of the interposition of (or crossing of) a physical geographic barrier such as a river. Also called geographic speciation. (Contrast with sympatric speciation.)

allopolyploidy The possession of more than two chromosome sets that are derived from more than one species.

allosteric regulation (al lo steer' ik) [Gk. *allos*: other + *stereos*: structure] Regulation of the activity of a protein (usually an enzyme) by the binding of an effector molecule to a site other than the active site.

alpha diversity Species diversity within a single community or habitat. (Contrast with beta diversity, gamma diversity.)

α (alpha) helix A prevalent type of secondary protein structure; a right-handed spiral.

alternation of generations The succession of multicellular haploid and diploid phases in some sexually reproducing organisms, notably plants.

alternative splicing A process for generating different mature mRNAs from a single gene by splicing together different sets of exons during RNA processing.

altruism Pertaining to behavior that benefits other individuals at a cost to the individual who performs it.

alveolus (al ve' o lus) (plural: alveoli) [L. *alveus*: cavity] A small, baglike cavity, especially the blind sacs of the lung.

amensalism (a men' sul ism) Interaction in which one animal is harmed and the other is unaffected. (Contrast with commensalism, mutualism.)

amine An organic compound containing an amino group (NH₂).

amino acid An organic compound containing both NH₂ and COOH groups. Proteins are polymers of amino acids.

amino acid replacement A change in the nucleotide sequence that results in one amino acid being replaced by another.

ammonotelic (am moan' o teel' ic) [Gk. *telos*: end] Pertaining to an organism in which the final product of breakdown of nitrogen-containing compounds (primarily proteins) is *ammonia*. (Contrast with ureotelic, uricotelic.)

amnion (am' nee on) The fluid-filled sac within which the embryos of reptiles (including birds) and mammals develop.

amniote egg A shelled egg surrounding four extraembryonic membranes and embryo-nourishing yolk. This evolutionary adaptation permitted mammals and reptiles to live and reproduce in drier environments than can most amphibians.

amphipathic (am' fi path' ic) [Gk. *amphi*: both + *pathos*: emotion] Of a molecule, having both hydrophilic and hydrophobic regions.

amplitude The magnitude of change over the course of a regular cycle.

amygdala A component of the limbic system that is involved in fear and fear memory.

amylase (am' ill ase) An enzyme that catalyzes the hydrolysis of starch, usually to maltose or glucose.

anabolic reaction (an uh bah' lik) [Gk. *ana*: upward + *ballein*: to throw] A synthetic reaction in which simple molecules are linked to form more complex ones; requires an input of energy and captures it in the chemical bonds that are formed. (Contrast with catabolic reaction.)

anaerobic (an ur row' bic) [Gk. *an*: not + *aer*: air + *bios*: life] Occurring without the use of molecular oxygen, O₂. (Contrast with aerobic.)

analogy (a nal' o jee) [Gk. *analogia*: resembling] A resemblance between two features that is due to convergent evolution rather than to common ancestry. The structures are said to be *analogous*, and each is an *analog* of the others. (Contrast with homology.)

anaphase (an' a phase) [Gk. *ana*: upward] The stage in cell nuclear division at which the first separation of sister chromatids (or, in the first meiotic division, of paired homologs) occurs.

ancestral trait The trait originally present in the ancestor of a given group; may be retained or changed in the descendants of that ancestor.

androgen (an' dro jen) Any of the several male sex steroids (most notably testosterone).

aneuploidy (an' you ploy dee) A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing pe-

ripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

angular gyrus A part of the human brain believed to be essential for integrating spoken and written language.

animal hemisphere The metabolically active upper portion of some animal eggs, zygotes, and embryos; does not contain the dense nutrient yolk. (Contrast with vegetal hemisphere.)

anion (an' eye on) [Gk. *ana*: upward progress] A negatively charged ion. (Contrast with cation.)

anisogamous (an eye sog' a muss) [Gk. *aniso*: unequal + *gamos*: marriage] Having morphologically dissimilar male and female gametes. (Contrast with isogamous.)

annual A plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

antagonistic interactions Interactions between two species in which one species benefits and the other is harmed. Includes predation, herbivory, and parasitism.

antenna system In photosynthesis, a group of different molecules that cooperate to absorb light energy and transfer it to a reaction center.

anterior Toward or pertaining to the tip or headward region of the body axis. (Contrast with posterior.)

anterior pituitary The portion of the vertebrate pituitary gland that derives from gut epithelium and produces tropic hormones.

anther (an' thur) [Gk. *anthos*: flower] A pollen-bearing portion of the stamen of a flower.

antheridium (an' thur id' ee um) [Gk. *antheros*: blooming] The multicellular structure that produces the sperm in nonvascular land plants and ferns.

antibody One of the myriad proteins produced by the immune system that specifically binds to a foreign substance in blood or other tissue fluids and initiates its removal from the body.

anticodon The three nucleotides in transfer RNA that pair with a complementary triplet (a codon) in messenger RNA.

antidiuretic hormone (ADH) A hormone that promotes water reabsorption by the kidney. ADH is produced by neurons in the hypothalamus and released from nerve terminals in the posterior pituitary. Also called vasopressin.

antigen (an' ti jun) Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

antigenic determinant The specific region of an antigen that is recognized and bound by a specific antibody. Also called an epitope.

antiparallel Pertaining to molecular orientation in which a molecule or parts of a molecule have opposing directions.

antiporter A membrane transport protein that moves one substance in one direction and another in the opposite direction. (Contrast with symporter, uniporter.)

antisense RNA A single-stranded RNA molecule complementary to, and thus targeted against, an mRNA of interest to block its translation.

anus (a' nus) An opening through which solid digestive wastes are expelled, located at the posterior end of a tubular gut.

aorta (a or' tah) [Gk. *aorte*: aorta] The main trunk of the arteries leading to the systemic (as opposed to the pulmonary) circulation.

aortic body A chemosensor in the aorta that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

aortic valve A one-way valve between the left ventricle of the heart and the aorta that prevents backflow of blood into the ventricle when it relaxes.

apex (a' pecks) The tip or highest point of a structure, as of a growing stem or root.

aphasia a deficit in the ability to use or understand words.

apical (a' pi kul) Pertaining to the *apex*, or tip, usually in reference to plants.

apical dominance In plants, inhibition by the apical bud of the growth of axillary buds.

apical hook A form taken by the stems of many eudicot seedlings that protects the delicate shoot apex while the stem grows through the soil.

apical meristem The meristem at the tip of a shoot or root; responsible for a plant's primary growth.

apomixis (ap oh mix' is) [Gk. *apo*: away from + *mixis*: sexual intercourse] The asexual production of seeds.

apoplast (ap' oh plast) In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

apoptosis (ap uh toh' sis) A series of genetically programmed events leading to cell death.

aposematism Warning coloration; bright colors or striking patterns of toxic or mimetic prey species that act as a warning to predators.

appendix In the human digestive system, the vestigial equivalent of the cecum, which serves no digestive function.

aquaporin A transport protein in plant and animal cell membranes through which water passes in osmosis.

aquatic (a kwa' tic) [L. *aqua*: water] Pertaining to or living in water. (Contrast with marine, terrestrial.)

aqueous (a' kwee us) Pertaining to water or a watery solution.

aquifer A large pool of groundwater.

archegonium (ar' ke go' nee um) The multicellular structure that produces eggs in nonvascular land plants, ferns, and gymnosperms.

archenteron (ark en' ter on) [Gk. *archos*: first + *enteron*: bowel] The earliest primordial animal digestive tract.

area phylogenies Phylogenies in which the names of the taxa are replaced with the names of the places where those taxa live or lived.

arms race A series of reciprocal adaptations between species involved in antagonistic interactions, in which adaptations that increase the fitness of a consumer species exert selection pressure on its resource species to counter the consumer's adaptation, and vice versa.

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

artery A muscular blood vessel carrying oxygenated blood away from the heart to other parts of the body. (Contrast with vein.)

artificial selection The selection by plant and animal breeders of individuals with certain desirable traits.

ascus (ass' cus) (plural: asci) [Gk. *askos*: bladder] In sac fungi, the club-shaped sporangium within which spores (ascospores) are produced by meiosis.

asexual reproduction Reproduction without sex.

assisted reproductive technologies (ARTs) Any of several procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in a female's reproductive tract for development.

association cortex In the vertebrate brain, the portion of the cortex involved in higher-order information processing, so named because it integrates, or associates, information from different sensory modalities and from memory.

associative learning A form of learning in which two unrelated stimuli become linked to the same response.

astrocyte [Gk. *astron*: star] A type of glial cell that contributes to the blood-brain barrier by surrounding the smallest, most permeable blood vessels in the brain.

atherosclerosis (ath' er oh sklair oh' sis) [Gk. *athero*: gruel, porridge + *skleros*: hard] A disease of the lining of the arteries characterized by fatty, cholesterol-rich deposits in the walls of the arteries. When fibroblasts infiltrate these deposits and calcium precipitates in them, the disease becomes arteriosclerosis, or "hardening of the arteries."

atom [Gk. *atomos*: indivisible] The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

atomic mass See atomic weight.

atomic number The number of protons in the nucleus of an atom; also equals the number of electrons around the neutral atom. Determines the chemical properties of the atom.

atomic weight The average of the mass numbers of a representative sample of atoms of an element, with all the isotopes in their normally occurring proportions. Also called atomic mass.

ATP (adenosine triphosphate) An energy-storage compound containing adenine, ribose, and three phosphate groups. When it is formed from ADP, useful energy is stored; when it is broken down (to ADP or AMP), energy is released to drive endergonic reactions.

ATP synthase An integral membrane protein that couples the transport of protons with the formation of ATP.

atrial natriuretic peptide A hormone released by the atrial muscle fibers of the heart when they are overly stretched, which decreases reabsorption of sodium by the kidney and thus blood volume.

atrioventricular node A modified node of cardiac muscle that organizes the action potentials that control contraction of the ventricles.

atrium (a' tree um) [L. *atrium*: central hall] An internal chamber. In the hearts of vertebrates, the thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

auditory system A sensory system that uses mechanoreceptors to convert pressure waves into receptor potentials; includes structures that gather sound waves, direct them to a sensory or-

gan, and amplify their effect on the mechanoreceptors.

autocatalysis [Gk. *autos*: self + *kata*: to break down] A positive feedback process in which an activated enzyme acts on other inactive molecules of the same enzyme to activate them.

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

autoimmunity An immune response by an organism to its own molecules or cells.

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls such involuntary functions as those of guts and glands. Also called the involuntary nervous system.

autopolyploidy The possession of more than two entire chromosome sets that are derived from a single species.

autosome Any chromosome (in a eukaryote) other than a sex chromosome.

autotroph (au' tow trowf') [Gk. *autos*: self + *trophe*: food] An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight (photoautotrophs) or chemically reduced matter (see chemolithotrophs). (Contrast with heterotroph.)

auxin (awk' sin) [Gk. *auxein*: to grow] In plants, a substance (the most common being indoleacetic acid) that regulates growth and various aspects of development.

avirulence (Avr) genes Genes in a pathogen that may trigger defenses in plants. See gene-for-gene resistance.

Avogadro's number The number of atoms or molecules in a mole (weighed out in grams) of a substance, calculated to be 6.022×10^{23} .

axillary bud A bud that forms in the angle (axil) where a leaf meets a stem.

axon [Gk. *axle*] The part of a neuron that conducts action potentials away from the cell body.

axon hillock The junction between an axon and its cell body, where action potentials are generated.

axon terminals The endings of an axon; they form synapses and release neurotransmitter.

- B -

B cell A type of lymphocyte involved in the humoral immune response of vertebrates. Upon recognizing an antigenic determinant, a B cell develops into a plasma cell, which secretes an antibody. (Contrast with T cell.)

bacillus (bah sil' us) [L: little rod] Any of various rod-shaped bacteria.

bacterial artificial chromosome (BAC) A DNA cloning vector used in bacteria that can carry up to 150,000 base pairs of foreign DNA.

bacteriophage (bak teer' ee o fayj) [Gk. *bakterion*: little rod + *phagein*: to eat] Any of a group of viruses that infect bacteria. Also called phage.

bacteroids Nitrogen-fixing organelles that develop from endosymbiotic bacteria.

bark All tissues external to the vascular cambium of a plant.

baroreceptor [Gk. *baros*: weight] A pressure-sensing cell or organ. Sometimes called a stress receptor.

basal body A centriole found at the base of a eukaryotic flagellum or cilium.

basal metabolic rate (BMR) The minimum rate of energy turnover in an awake (but resting) bird or mammal that is not expending energy for thermoregulation.

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar-phosphate backbone.

base pair (bp) In double-stranded DNA, a pair of nucleotides formed by the *complementary base pairing* of a purine on one strand and a pyrimidine on the other.

basic Having a pH greater than 7.0 (i.e., having a hydrogen ion concentration lower than 10^{-7} molar). (Contrast with acidic.)

basidiocarp A fruiting structure produced by club fungi.

basidium (bass id' ee yum) In club fungi, the characteristic sporangium in which four spores are formed by meiosis and then borne externally before being shed.

basilar membrane A membrane in the human inner ear whose flexion in response to sound waves activates hair cells; flexes at different locations in response to different pitches of sound.

basophil A type of phagocytic white blood cell that releases histamine and may promote T cell development.

Batesian mimicry The convergence in appearance of an edible species (mimic) with an unpalatable species (model).

benefit An improvement in survival and reproductive success resulting from performing a behavior or having a trait. (Contrast with cost.)

benthic zone [Gk. *benthos*: bottom] The bottom of the ocean.

beta diversity Between-habitat diversity; a measure of the change in species composition from one community or habitat to another. (Contrast with alpha diversity, gamma diversity.)

β (beta) pleated sheet A type of protein secondary structure; results from hydrogen bonding between polypeptide regions running antiparallel to each other.

biennial A plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

bilateral symmetry The condition in which only the right and left sides of an organism, divided by a single plane through the midline, are mirror images of each other.

bilayer A structure that is two layers in thickness. In biology, most often refers to the phospholipid bilayer of membranes. (See phospholipid bilayer.)

bile A secretion of the liver made up of bile salts synthesized from cholesterol, various phospholipids, and bilirubin (the breakdown product of hemoglobin). Emulsifies fats in the small intestine.

binary fission Reproduction of a prokaryote by division of a cell into two comparable progeny cells.

binocular vision Overlapping visual fields of an animal's two eyes; allows the animal to see in three dimensions.

binomial nomenclature A taxonomic naming system in which each species is given two names (a genus name followed by a species name).

biofilm A community of microorganisms embedded in a polysaccharide matrix, forming a highly resistant coating on almost any moist surface.

biogeochemical cycle Movement of inorganic elements such as nitrogen, phosphorus, and carbon through living organisms and the physical environment.

biogeographic region One of several defined, continental-scale regions of Earth, each of which has a biota distinct from that of the others. (Contrast with biome.)

biogeography The scientific study of the patterns of distribution of populations, species, and ecological communities across Earth.

bioinformatics The use of computers and/or mathematics to analyze complex biological information, such as DNA sequences.

biological species concept The definition of a species as a group of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups. (Contrast with lineage species concept; morphological species concept.)

biology [Gk. *bios*: life + *logos*: study] The scientific study of living things.

bioluminescence The production of light by biochemical processes in an organism.

biomass The total weight of all the organisms, or some designated group of organisms, in a given area.

biome (bye' ome) A major division of the ecological communities of Earth, characterized primarily by distinctive vegetation. A given biogeographic region contains many different biomes.

bioremediation The use by humans of other organisms to remove contaminants from the environment.

biosphere (bye' oh sphere) All regions of Earth (terrestrial and aquatic) and Earth's atmosphere in which organisms can live.

biota (bye oh' tah) All of the organisms—animals, plants, fungi, and microorganisms—found in a given area. (Contrast with flora, fauna.)

biotechnology The use of cells or living organisms to produce materials useful to humans.

biotic (bye ah' tick) [Gk. *bios*: life] Alive. (Contrast with abiotic.)

biotic interchange The dispersal of species from two different biotas into the region they had not previously inhabited, as when two formerly separated land masses fuse.

blade The thin, flat portion of a leaf.

blastocoel (blass' toe seal) [Gk. *blastos*: sprout + *koiolos*: hollow] The central, hollow cavity of a blastula.

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

blastodisc (blass' toe disk) An embryo that forms as a disk of cells on the surface of a large yolk mass; comparable to a blastula, but occurring in animals such as birds and reptiles, in which the massive yolk restricts incomplete cleavage.

blastomere Any of the cells produced by the early divisions of a fertilized animal egg.

blastula (blass' chu luh) An early stage of the animal embryo; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

block to polyspermy Any of several responses to entry of a sperm into an egg that prevent more than one sperm from entering the egg.

blood A fluid tissue that is pumped around the body; a component of the circulatory system.

blood-brain barrier A property of blood vessels in the brain that prevents most chemicals from diffusing from the blood into the brain.

blue-light receptors Pigments in plants that absorb blue light (400–500 nm). These pigments mediate many plant responses including phototropism, stomatal movements, and expression of some genes.

body plan The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts.

bond See chemical bond.

bottleneck See population bottleneck.

bone A rigid component of vertebrate skeletal systems that contains an extracellular matrix of insoluble calcium phosphate crystals as well as collagen fibers.

Bowman's capsule An elaboration of the renal tubule, composed of podocytes, that surrounds and collects the filtrate from the glomerulus.

brain The centralized integrative center of a nervous system.

brainstem The portion of the vertebrate brain between the spinal cord and the forebrain, made up of the medulla, pons, and midbrain.

brassinosteroids Plant steroid hormones that mediate light effects promoting the elongation of stems and pollen tubes.

Broca's area A portion of the human brain essential for speech. Located in the frontal lobe just in front of the primary motor cortex.

bronchioles The smallest airways in a vertebrate lung, branching off the bronchi.

bronchus (plural: bronchi) The major airway(s) branching off the trachea into the vertebrate lung.

brown fat In mammals, fat tissue that is specialized to produce heat. It has many mitochondria and capillaries, and a protein that uncouples oxidative phosphorylation.

budding Asexual reproduction in which a more or less complete new organism grows from the body of the parent organism, eventually detaching itself.

buffer A substance that can transiently accept or release hydrogen ions and thereby resist changes in pH.

bulbourethral glands Secretory structures of the human male reproductive system that produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen.

bulk flow The movement of a solution from a region of higher pressure potential to a region of lower pressure potential.

bundle of His Fibers of modified cardiac muscle that conduct action potentials from the atria to the ventricular muscle mass.

bundle sheath cell Part of a tissue that surrounds the veins of plants; contains chloroplasts in C₄ plants.

- C -

C3 plants Plants that produce 3PG as the first stable product of carbon fixation in photosynthesis and use ribulose biphosphate as a CO₂ receptor.

C4 plants Plants that produce oxaloacetate as the first stable product of carbon fixation in photosynthesis and use phosphoenolpyruvate as CO₂ acceptor. C₄ plants also perform the reactions of C₃ photosynthesis.

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and promotes bone formation. (Contrast with parathyroid hormone.)

calorie [L. *calor*: heat] The amount of heat required to raise the temperature of 1 gram of water by 1°C. Physiologists commonly use the kilocalorie (kcal) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie, but refer to it as the *Calorie* (capital C).

Calvin cycle The stage of photosynthesis in which CO₂ reacts with RuBP to form 3PG, 3PG is reduced to a sugar, and RuBP is regenerated, while other products are released to the rest of the plant. Also known as the Calvin-Benson cycle.

calyx (kay' licks) [Gk. *kalyx*: cup] All of the sepals of a flower, collectively.

CAM See crassulacean acid metabolism.

Cambrian explosion The rapid diversification of multicellular life that took place during the Cambrian period.

cAMP (cyclic AMP) A compound formed from ATP that acts as a second messenger.

cancellous bone A type of bone with numerous internal cavities that make it appear spongy, although it is rigid. (Contrast with compact bone.)

canopy The leaf-bearing part of a tree. Collectively, the aggregate of the leaves and branches of the larger woody plants of an ecological community.

capillaries [L. *capillaris*: hair] Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins. Capillaries are the site of exchange of materials between the blood and the interstitial fluid.

capsid The outer shell of a virus that encloses its nucleic acid.

carbohydrates Organic compounds containing carbon, hydrogen, and oxygen in the ratio 1:2:1 (i.e., with the general formula C_nH_{2n}O_n). Common examples are sugars, starch, and cellulose.

carbon skeleton The chains or rings of carbon atoms that form the structural basis of organic molecules. Other atoms or functional groups are attached to the carbon atoms.

carboxylase An enzyme that catalyzes the addition of carboxyl groups to a substrate.

cardiac (kar' dee ak) [Gk. *kardia*: heart] Pertaining to the heart and its functions.

cardiac cycle Contraction of the two atria of the heart, followed by contraction of the two ventricles and then relaxation.

cardiac muscle A type of muscle tissue that makes up, and is responsible for the beating of, the heart. Characterized by branching cells with single nuclei and a striated (striped) appearance. (Contrast with smooth muscle, skeletal muscle.)

cardiovascular system [Gk. *kardia*: heart + L. *vasculum*: small vessel] The heart, blood, and vessels are of a circulatory system.

carnivore [L. *carn*: flesh + *vovare*: to devour] An organism that eats animal tissues. (Contrast with detritivore, herbivore, omnivore.)

carotenoid (ka rah' tuh noid) A yellow, orange, or red lipid pigment commonly found as an ac-

cessory pigment in photosynthesis; also found in fungi.

carotid body A chemosensor in the carotid artery that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

carpel (kar' pel) [Gk. *karpos*: fruit] The organ of the flower that contains one or more ovules.

carrier (1) In facilitated diffusion, a membrane protein that binds a specific molecule and transports it through the membrane. (2) In respiratory and photosynthetic electron transport, a participating substance such as NAD that exists in both oxidized and reduced forms. (3) In genetics, a person heterozygous for a recessive trait.

carrying capacity (K) The number of individuals in a population that the resources of its environment can support.

cartilage In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

cartilage bone A type of bone that begins its development as a cartilaginous structure resembling the future mature bone, then gradually hardens into mature bone. (Contrast with membranous bone.)

Casparian strip A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

caspase One of a group of proteases that catalyze cleavage of target proteins and are active in apoptosis.

catabolic reaction (kat uh bah' lik) [Gk. *kata*: to break down + *ballein*: to throw] A synthetic reaction in which complex molecules are broken down into simpler ones and energy is released. (Contrast with anabolic reaction.)

catabolite repression In the presence of abundant glucose, the diminished synthesis of catabolic enzymes for other energy sources.

catalyst (kat' a list) [Gk. *kata*: to break down] A chemical substance that accelerates a reaction without itself being consumed in the overall course of the reaction. Catalysts lower the activation energy of a reaction. Enzymes are biological catalysts.

cation (cat' eye on) An ion with one or more positive charges. (Contrast with anion.)

caudal [L. *cauda*: tail] Pertaining to the tail, or to the posterior part of the body.

cDNA See complementary DNA.

cDNA library A collection of complementary DNAs derived from mRNAs of a particular tissue at a particular time in the life cycle of an organism.

cecum (see' cum) [L. blind] A blind branch off the large intestine. In many nonruminant mammals, the cecum contains a colony of microorganisms that contribute to the digestion of food.

cell The simplest structural unit of a living organism. In multicellular organisms, the building blocks of tissues and organs.

cell adhesion molecules Molecules on animal cell surfaces that affect the selective association of cells into tissues during development of the embryo.

cell cycle The stages through which a cell passes between one division and the next. Includes all stages of interphase and mitosis.

cell division The reproduction of a cell to produce two new cells. In eukaryotes, this process

involves nuclear division (mitosis) and cytoplasmic division (cytokinesis).

cell fate The type of cell that an undifferentiated cell in an embryo will become in the adult.

cell junctions Specialized structures associated with the plasma membranes of epithelial cells. Some contribute to cell adhesion, others to intercellular communication.

cell recognition Binding of cells to one another mediated by membrane proteins or carbohydrates.

cell theory States that cells are the basic structural and physiological units of all living organisms, and that all cells come from preexisting cells.

cell wall A relatively rigid structure that encloses cells of plants, fungi, many protists, and most prokaryotes, and which gives these cells their shape and limits their expansion in hypotonic media.

cellular immune response Immune system response mediated by T cells and directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune response.)

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O_2 , generating H_2O and releasing energy.

cellulose (sell' you lowss) A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

central dogma The premise that information flows from DNA to RNA to polypeptide.

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

central vacuole In plant cells, a large organelle that stores the waste products of metabolism and maintains turgor.

centrifuge [L. *centrum*: center + *fugere*: to flee] A laboratory device in which a sample is spun around a central axis at high speed. Used to separate suspended materials of different densities.

centriole (sen' tree ole) A paired organelle that helps organize the microtubules in animal and protist cells during nuclear division.

centromere (sen' tro meer) [Gk. *centron*: center + *meros*: part] The region where sister chromatids join.

centrosome (sen' tro soam) The major microtubule organizing center of an animal cell.

cephalization (sef ah luh zay' shun) [Gk. *kephale*: head] The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

cerebellum (sair uh bell' um) [L. diminutive of *cerebrum*, brain] The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

cerebral cortex The thin layer of gray matter (neuronal cell bodies) that overlies the cerebrum.

cerebrum (su ree' brum) [L. brain] The dorsal anterior portion of the forebrain, making up the largest part of the brain of mammals; the chief coordination center of the nervous system; consists of two *cerebral hemispheres*.

cervix (sir' vix) [L. neck] The opening of the uterus into the vagina.

cGMP (cyclic guanosine monophosphate) An intracellular messenger that is part of signal transmission pathways involving G proteins. (See G protein.)

channel protein An integral membrane protein that forms an aqueous passageway across the membrane in which it is inserted through which specific solutes may pass.

chaperone A protein that guards other proteins by counteracting molecular interactions that threaten their three-dimensional structure.

character In genetics, an observable feature, such as eye color. (Contrast with trait.)

character displacement An evolutionary phenomenon in which species that compete for the same resources within the same territory tend to diverge in morphology and/or behavior.

chemical bond An attractive force stably linking two atoms.

chemical evolution The theory that life originated through the chemical transformation of inanimate substances.

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

chemical synapse Neural junction at which neurotransmitter molecules released from a presynaptic cell induce changes in a postsynaptic cell. (Contrast with electrical synapse.)

chemically gated channel A type of gated channel that opens or closes depending on the presence or absence of a specific molecule, which binds to the channel protein or to a separate receptor that in turn alters the three-dimensional shape of channel protein.

chemiosmosis Formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATP synthase activity.

chemoautotroph See chemolithotroph.

chemoheterotroph An organism that must obtain both carbon and energy from organic substances. (Contrast with chemolithotroph, photoautotroph, photoheterotroph.)

chemolithotroph [Gk. *lithos*: stone, rock] An organism that uses carbon dioxide as a carbon source and obtains energy by oxidizing inorganic substances from its environment; also called chemoautotroph. (Contrast with chemoheterotroph, photoautotroph, photoheterotroph.)

chemoreceptor A sensory receptor cell that senses specific molecules (such as odorant molecules or pheromones) in the environment.

chiasma (kie az' muh) (plural: chiasmata) [Gk. cross] An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

chlorophyll (klor' o fill) [Gk. *kloros*: green + *phylon*: leaf] Any of several green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

chloroplast [Gk. *chloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

choanocyte (ko' an uh site) The collared, flagellated feeding cells of sponges.

cholecystokinin (ko' luh sis tuh kai' nin) A hormone produced and released by the lining of the duodenum when it is stimulated by undigested fats and proteins. It stimulates the gallbladder to release bile and slows stomach activity.

chorion (kor' ee on) [Gk. *chorion*: afterbirth] The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

chromatid (kro' ma tid) A newly replicated chromosome, from the time molecular duplication occurs until the time the centromeres separate (during anaphase of mitosis or of meiosis II).

chromatin The nucleic acid-protein complex that makes up eukaryotic chromosomes.

chromosomal mutation Loss of or changes in position/direction of a DNA segment on a chromosome.

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

chylomicron (ky low my' cron) Particles of lipid coated with protein, produced in the gut from dietary fats and secreted into the extracellular fluids.

chyme (kime) [Gk. *kymus*: juice] Created in the stomach; a mixture of ingested food with the digestive juices secreted by the salivary glands and the stomach lining.

cilium (sil' ee um) (plural: cilia) [L. eyelash] Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than a flagellum.

circadian rhythm (sir kade' ee an) [L. *circa*: approximately + *dies*: day] A rhythm of growth or activity that recurs about every 24 hours.

circannual rhythm [L. *circa*: + *annus*: year] A rhythm of growth or activity that recurs on a yearly basis.

circulatory system A system consisting of a muscular pump (heart), a fluid (blood or hemolymph), and a series of conduits (blood vessels) that transports materials around the body.

citric acid cycle In cellular respiration, a set of chemical reactions whereby acetyl CoA is oxidized to carbon dioxide and hydrogen atoms are stored as NADH and FADH₂. Also called the Krebs cycle.

clade [Gk. *klados*: branch] A monophyletic group made up of an ancestor and all of its descendants.

class I MHC molecules Cell surface proteins that participate in the cellular immune response directed against virus-infected cells.

class II MHC molecules Cell surface proteins that participate in the cell-cell interactions (of T-helper cells, macrophages, and B cells) of the humoral immune response.

cleavage The first few cell divisions of an animal zygote. *See also* complete cleavage, incomplete cleavage.

climate The long-term average atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) found in a region.

climax community The final stage of succession; a community that is capable of perpetuating itself under local climatic and soil conditions and persists for a relatively long time.

clinal variation [Gk. *klinein*: to lean] Gradual change in the phenotype of a species over a geographic gradient.

clonal deletion Inactivation or destruction of lymphocyte clones that would produce immune reactions against the animal's own body.

clonal selection Mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

clone [Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

closed circulatory system Circulatory system in which the circulating fluid is contained within a continuous system of vessels. (Contrast with open circulatory system.)

coastal zone The marine life zone that extends from the shoreline to the edge of the continental shelf. Characterized by relatively shallow, well-oxygenated water and relatively stable temperatures and salinities.

coccus (kock' us) (plural: cocci) [Gk. *kokkos*: berry, pit] Any of various spherical or spheroidal bacteria.

cochlea (kock' lee uh) [Gk. *kokhlos*: snail] A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

codominance A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

codon Three nucleotides in messenger RNA that direct the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

coelom (see' loam) [Gk. *koiloma*: cavity] An animal body cavity, enclosed by muscular mesoderm and lined with a mesodermal layer called peritoneum that also surrounds the internal organs.

coenocytic (seen' a sit ik) [Gk. *koinos*: common + *kytos*: container] Referring to the condition, found in some fungal hyphae, of "cells" containing many nuclei but enclosed by a single plasma membrane. Results from nuclear division without cytokinesis.

coenzyme A nonprotein organic molecule that plays a role in catalysis by an enzyme.

coevolution Evolutionary processes in which an adaptation in one species leads to the evolution of an adaptation in a species with which it interacts; also known as reciprocal adaptation.

cofactor An inorganic ion that is weakly bound to an enzyme and required for its activity.

cohesin A protein involved in binding chromatids together.

cohesion The tendency of molecules (or any substances) to stick together.

cohort (co' hort) [L. *cohors*: company of soldiers] A group of similar-aged organisms.

coleoptile A sheath that surrounds and protects the shoot apical meristem and young primary

leaves of a grass seedling as they move through the soil.

collagen [Gk. *kolla*: glue] A fibrous protein found extensively in bone and connective tissue.

collecting duct In vertebrates, a tubule that receives urine produced in the nephrons of the kidney and delivers that fluid to the ureter for excretion.

collenchyma (cull eng' kyma) [Gk. *kolla*: glue + *enchyma*: infusion] A type of plant cell, living at functional maturity, which lends flexible support by virtue of primary cell walls thickened at the corners. (Contrast with parenchyma, sclerenchyma.)

colon [Gk. *kolon*] The large intestine.

commensalism [L. *com*: together + *mensa*: table] A type of interaction between species in which one participant benefits while the other is unaffected.

communication A signal from one organism (or cell) that alters the functioning or behavior of another organism (or cell).

community Any ecologically integrated group of species of microorganisms, plants, and animals inhabiting a given area.

compact bone A type of bone with a solid, hard structure. (Contrast with cancellous bone.)

companion cell In angiosperms, a specialized cell found adjacent to a sieve tube element.

comparative experiment Experimental design in which data from various unmanipulated samples or populations are compared, but in which variables are not controlled or even necessarily identified. (Contrast with controlled experiment.)

comparative genomics Computer-aided comparison of DNA sequences between different organisms to reveal genes with related functions.

competition In ecology, use of the same resource by two or more species when the resource is present in insufficient supply for the combined needs of the species.

competitive exclusion A result of competition between species for a limiting resource in which one species completely eliminates the other.

competitive inhibitor A nonsubstrate that binds to the active site of an enzyme and thereby inhibits binding of its substrate. (Contrast with noncompetitive inhibitor.)

complement system A group of eleven proteins that play a role in some reactions of the immune system. The complement proteins are not immunoglobulins.

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

complementary DNA (cDNA) DNA formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

complete cleavage Pattern of cleavage that occurs in eggs that have little yolk. Early cleavage furrows divide the egg completely and the blastomeres are of similar size. (Contrast with incomplete cleavage.)

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

compound (1) A substance made up of atoms of more than one element. (2) Made up of many units, as in the *compound eyes* of arthropods.

concerted evolution The common evolution of a family of repeated genes, such that changes in one copy of the gene family are replicated in other copies of the gene family.

condensation reaction A chemical reaction in which two molecules become connected by a covalent bond and a molecule of water is released ($AH + BOH \rightarrow AB + H_2O$). (Contrast with hydrolysis reaction.)

conditional mutation A mutation that results in a characteristic phenotype only under certain environmental conditions.

conduction The transfer of heat from one object to another through direct contact.

cone (1) In conifers, a reproductive structure consisting of spore-bearing scales extending from a central axis. (Contrast with strobilus.) (2) In the vertebrate retina, a type of photoreceptor cell responsible for color vision.

conidium (ko nid' ee um) (plural: conidia) [Gk. *konis*: dust] A type of haploid fungal spore borne at the tips of hyphae, not enclosed in sporangia.

conjugation (kon ju gay' shun) [L. *conjugare*: yoke together] (1) A process by which DNA is passed from one cell to another through a *conjugation tube*, as in bacteria. (2) A nonreproductive sexual process by which *Paramecium* and other ciliates exchange genetic material.

connective tissue A type of tissue that connects or surrounds other tissues; its cells are embedded in a collagen-containing matrix. One of the four major tissue types in multicellular animals.

connexon In a gap junction, a protein channel linking adjacent animal cells.

consensus sequences Short stretches of DNA that appear, with little variation, in many different genes.

conservation biology An applied science that carries out investigations with the aim of maintaining the diversity of life on Earth.

conserved Pertaining to a gene or trait that has evolved very slowly and is similar or even identical in individuals of highly divergent groups.

conspecifics Individuals of the same species.

constant region The portion of an immunoglobulin molecule whose amino acid composition determines its class and does not vary among immunoglobulins in that class. (Contrast with variable region.)

constitutive Always present; produced continually at a constant rate. (Contrast with inducible.)

consumer An organism that eats the tissues of some other organism.

continental drift The gradual movements of the world's continents that have occurred over billions of years.

contractile vacuole (kon trak' tul) A specialized vacuole that collects excess water taken in by osmosis, then contracts to expel the water from the cell.

controlled experiment An experiment in which a sample is divided into groups whereby experimental groups are exposed to manipulations of an independent variable while one group serves as an untreated control. The data from the various groups are then compared to see if there are changes in a dependent variable as a result of the

experimental manipulation. (Contrast with comparative experiment.)

convection The transfer of heat to or from a surface via a moving stream of air or fluid.

convergent evolution Independent evolution of similar features from different ancestral traits.

copulation Reproductive behavior that results in a male depositing sperm in the reproductive tract of a female.

cork cambium [L. *cambiare*: to exchange] In plants, a lateral meristem that produces secondary growth, mainly in the form of waxy-walled protective cells, including some of the cells that become bark.

cornea The clear, transparent tissue that covers the eye and allows light to pass through to the retina.

corolla (ko role' lah) [L. *corolla*: a small crown] All of the petals of a flower, collectively.

coronary artery (kor' oh nair ee) An artery that supplies blood to the heart muscle.

coronary thrombosis A fibrous clot that blocks a coronary artery.

corpus luteum (kor' pus loo' tee um) (plural: corpora lutea) [L. yellow body] A structure formed from a follicle after ovulation; produces hormones important to the maintenance of pregnancy.

corridor A connection between habitat patches through which organisms can disperse; plays a critical role in maintaining subpopulations.

cortex [L. *cortex*: covering, rind] (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal gland (adrenal cortex) and the brain (cerebral cortex).

corticosteroids Steroid hormones produced and released by the cortex of the adrenal gland.

corticotropin A tropic hormone produced by the anterior pituitary hormone that stimulates cortisol release from the adrenal cortex. Also called adrenocorticotrophic hormone (ACTH).

corticotropin-releasing hormone A releasing hormone produced by the hypothalamus that controls the release of cortisol from the anterior pituitary.

cortisol A corticosteroid that mediates stress responses.

cost-benefit analysis An approach to evolutionary studies that assumes an animal has a limited amount of time and energy to devote to each of its activities, and that each activity has fitness costs as well as benefits. (See also trade-off.)

cotyledon (kot' ul lee' dun) [Gk. *kotyledon*: hollow space] A "seed leaf." An embryonic organ that stores and digests reserve materials; may expand when seed germinates.

countercurrent flow An arrangement that promotes the maximum exchange of heat, or of a diffusible substance, between two fluids by having the fluids flow in opposite directions through parallel vessels close together.

countercurrent multiplier The mechanism that increases the concentration of the interstitial fluid in the mammalian kidney through countercurrent flow in the loops of Henle and selective permeability and active transport of ions by segments of the loops of Henle.

covalent bond Chemical bond based on the sharing of electrons between two atoms.

CpG islands DNA regions rich in C residues adjacent to G residues. Especially abundant in promoters, these regions are where methylation of cytosine usually occurs.

crassulacean acid metabolism (CAM) A metabolic pathway enabling the plants that possess it to store carbon dioxide at night and then perform photosynthesis during the day with stomata closed.

critical night length In the photoperiodic flowering response of short-day plants, the length of night above which flowering occurs and below which the plant remains vegetative. (The reverse applies in the case of long-day plants.)

critical period See sensitive period.

cross section A section taken perpendicular to the longest axis of a structure. Also called a transverse section.

crossing over The mechanism by which linked genes undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

cryptsis [Gk. *kryptos*: hidden] The resemblance of an organism to some part of its environment, which helps it to escape detection by enemies.

cryptochromes [Gk. *kryptos*: hidden + *kroma*: color] Photoreceptors mediating some blue-light effects in plants and animals.

ctene (teen) [Gk. *cteis*: comb] In ctenophores, a comblike row of cilia-bearing plates. Ctenophores move by beating the cilia on their eight ctenes.

culture (1) A laboratory association of organisms under controlled conditions. (2) The collection of knowledge, tools, values, and rules that characterize a human society.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

cyclic AMP See cAMP.

cyclic electron transport In photosynthetic light reactions, the flow of electrons that produces ATP but no NADPH or O_2 .

cyclin A protein that activates a cyclin-dependent kinase, bringing about transitions in the cell cycle.

cyclin-dependent kinase (Cdk) A protein kinase whose target proteins are involved in transitions in the cell cycle and which is active only when complexed with additional protein subunits, called cyclins.

cytokine A regulatory protein made by immune system cells that affects other target cells in the immune system.

cytokinesis (sy' toe kine ee' sis) [Gk. *kytos*: container + *kinein*: to move] The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

cytokinin (sy' toe kine' in) A member of a class of plant growth substances that plays roles in senescence, cell division, and other phenomena.

cytoplasm The contents of the cell, excluding the nucleus.

cytoplasmic determinants In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

cytoplasmic segregation The asymmetrical distribution of cytoplasmic determinants in a developing animal embryo.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

cytoskeleton The network of microtubules and microfilaments that gives a eukaryotic cell its shape and its capacity to arrange its organelles and to move.

cytosol The fluid portion of the cytoplasm, excluding organelles and other solids.

cytotoxic T cells (T_C) Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with T-helper cells.)

- D -

DAG See diacylglycerol.

daughter chromosomes During mitosis, the separated chromatids from the beginning of anaphase onward.

dead space The lung volume that fails to be ventilated with fresh air (because the lungs are never completely emptied during exhalation).

deciduous [L. *deciduus*: falling off] Pertaining to a woody plant that sheds its leaves but does not die.

declarative memory Memory of people, places, events, and things that can be consciously recalled and described. (Contrast with procedural memory.)

decomposer An organism that metabolizes organic compounds in debris and dead organisms, releasing inorganic material; found among the bacteria, protists, and fungi. See also detritivore, saprobe.

defensin A type of protein made by phagocytes that kills bacteria and enveloped viruses by insertion into their plasma membranes.

degeneracy The situation in which a single amino acid may be represented by any of two or more different codons in messenger RNA. Most of the amino acids can be represented by more than one codon.

deletion A mutation resulting from the loss of a continuous segment of a gene or chromosome. Such mutations almost never revert to wild type. (Contrast with duplication, point mutation.)

demethylase An enzyme that catalyzes the removal of the methyl group from cytosine, reversing DNA methylation.

demography The study of population structure and of the processes by which it changes.

denaturation Loss of activity of an enzyme or nucleic acid molecule as a result of structural changes induced by heat or other means.

dendrite [Gk. *dendron*: tree] A fiber of a neuron which often cannot carry action potentials. Usually much branched and relatively short compared with the axon, and commonly carries information to the cell body of the neuron.

denitrification Metabolic activity by which nitrate and nitrite ions are reduced to form nitrogen gas; carried by certain soil bacteria.

denitrifiers Bacteria that release nitrogen to the atmosphere as nitrogen gas (N₂).

density-dependent Pertaining to a factor with an effect on population size that increases in proportion to population density.

density-independent Pertaining to a factor with an effect on population size that acts independently of population density.

deoxyribonucleic acid See DNA.

deoxyribose A five-carbon sugar found in nucleotides and DNA.

depolarization A change in the resting potential across a membrane so that the inside of the cell becomes less negative, or even positive, compared with the outside of the cell. (Contrast with hyperpolarization.)

derived trait A trait that differs from the ancestral trait. (Contrast with shared derived trait.)

dermal tissue system The outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system and vascular tissue system.)

desmosome (dez' mo sowm) [Gk. *desmos*: bond + *soma*: body] An adhering junction between animal cells.

desmotubule A membrane extension connecting the endoplasmic reticulum of two plant cells that traverses the plasmodesma.

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set.

determinate growth A growth pattern in which the growth of an organism or organ ceases when an adult state is reached; characteristic of most animals and some plant organs. (Contrast with indeterminate growth.)

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products of other organisms.

developmental module A functional entity in the embryo encompassing genes and signaling pathways that determine a physical structure independently of other such modules.

developmental plasticity The capacity of an organism to alter its pattern of development in response to environmental conditions.

diacylglycerol (DAG) In hormone action, the second messenger produced by hydrolytic removal of the head group of certain phospholipids.

diapause A period of developmental or reproductive arrest, entered in response to day length, that enables an organism to better survive.

diaphragm (dye' uh fram) [Gk. *diaphrassein*: barricade] (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking the entry of sperm.

diastole (dye ass' toll ee) [Gk. *dilation*] The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

diencephalon The portion of the vertebrate forebrain that develops into the thalamus and hypothalamus.

differential gene expression The hypothesis that, given that all cells contain all genes, what makes one cell type different from another is the difference in transcription and translation of those genes.

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

diffuse coevolution The evolution of similar traits in suites of species experiencing similar selection pressures imposed by other suites of species with which they interact.

diffusion Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present.

dihybrid cross A mating in which the parents differ with respect to the alleles of two loci of interest.

dikaryon (di care' ee ahn) [Gk. *di*: two + *karyon*: kernel] A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

diploblastic Having two cell layers. (Contrast with triploblastic.)

diploid (dip' loid) [Gk. *diplos*: double] Having a chromosome complement consisting of two copies (homologs) of each chromosome. Designated $2n$.

diplontic A type of life cycle in which gametes are the only haploid cells and mitosis occurs only in diploid cells. (Contrast with haplontic.)

direct transduction A cell signaling mechanism in which the receptor acts as the effector in the cellular response. (Contrast with indirect transduction.)

directional selection Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection, stabilizing selection.)

disaccharide A carbohydrate made up of two monosaccharides (simple sugars).

dispersal Movement of organisms away from a parent organism or from an existing population.

dispersion The distribution of individuals in space within a population.

disruptive selection Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection; stabilizing selection.)

distal Away from the point of attachment or other reference point. (Contrast with proximal.)

distal convoluted tubule The portion of a renal tubule from where it reaches the renal cortex, just past the loop of Henle to where it joins a collecting duct. (Compare with proximal convoluted tubule.)

disturbance A short-term event that disrupts populations, communities, or ecosystems by changing the environment.

disulfide bridge The covalent bond between two sulfur atoms (—S—S—) linking two molecules or remote parts of the same molecule.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

DNA fingerprint An individual's unique pattern of allele sequences, commonly short tandem repeats and single nucleotide polymorphisms.

DNA helicase An enzyme that functions to unwind the double helix.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

DNA methylation The addition of methyl groups to bases in DNA, usually cytosine or guanine.

DNA methyltransferase An enzyme that catalyzes the methylation of DNA.

DNA microarray A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed so that hybridization of cell-derived RNA or DNA to the target sequences can be performed.

DNA polymerase Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

DNA topoisomerase An enzyme that unwinds and winds coils of DNA that form during replication and transcription.

docking protein A receptor protein that binds (docks) a ribosome to the membrane of the endoplasmic reticulum by binding the signal sequence attached to a new protein being made at the ribosome.

domain (1) An independent structural element within a protein. Encoded by recognizable nucleotide sequences, a domain often folds separately from the rest of the protein. Similar domains can appear in a variety of different proteins across phylogenetic groups (e.g., “homeobox domain”; “calcium-binding domain”). (2) In phylogenetics, the three monophyletic branches of life (Bacteria, Archaea, and Eukarya).

dominance In genetics, the ability of one allelic form of a gene to determine the phenotype of a heterozygous individual in which the homologous chromosomes carry both it and a different (recessive) allele. (Contrast with recessive.)

dormancy A condition in which normal activity is suspended, as in some spores, seeds, and buds.

dorsal [L. *dorsum*: back] Toward or pertaining to the back or upper surface. (Contrast with ventral.)

dorsal lip In amphibian embryos, the dorsal segment of the blastopore. Also called the “organizer,” this region directs the development of nearby embryonic regions.

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm’s nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg’s two polar nuclei to produce the first cell of the triploid endosperm (the tissue that will nourish the growing plant embryo).

double helix Refers to DNA and the (usually right-handed) coil configuration of two complementary, antiparallel strands.

downregulation A negative feedback process in which continuous high concentrations of a hormone can decrease the number of its receptors. (Contrast with upregulation.)

duodenum (do’ uh dee’ num) The beginning portion of the vertebrate small intestine. (Contrast with ileum, jejunum.)

duplication A mutation in which a segment of a chromosome is duplicated, often by the attachment of a segment lost from its homolog. (Contrast with deletion.)

- E -

ecdysone (eck die’ sone) [Gk. *ek*: out of + *dyo*: to clothe] In insects, a hormone that induces molting.

ecological efficiency The overall transfer of energy from one trophic level to the next, expressed as the ratio of consumer production to producer production.

ecology [Gk. *oikos*: house] The scientific study of the interaction of organisms with their living (biotic) and nonliving (abiotic) environments.

ecosystem (eek’ oh sis tum) The organisms of a particular habitat, such as a pond or forest, together with the physical environment in which they live.

ecosystem engineer An organism that builds structures that alter existing habitats or create new habitats.

ecosystem services Processes by which ecosystems maintain resources that benefit human society.

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

ectotherm [Gk. *ektos*: outside + *thermos*: heat] An animal that is dependent on external heat sources for regulating its body temperature (Contrast with endotherm.)

edema (i dee’ mah) [Gk. *oidema*: swelling] Tissue swelling caused by the accumulation of fluid.

edge effect The changes in ecological processes in a community caused by physical and biological factors originating in an adjacent community.

effector protein In cell signaling, a protein responsible for the cellular response to a signal transduction pathway.

efferent (ef’ ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in a neuron that carries impulses outward from the central nervous system (efferent neuron), or a blood vessel that carries blood away from a structure. (Contrast with afferent.)

egg In all sexually reproducing organisms, the female gamete; in birds, reptiles, and some other vertebrates, a structure within which early embryonic development occurs. *See also* amniote egg, ovum.

electrical synapse A type of synapse at which action potentials spread directly from presynaptic cell to postsynaptic cell. (Contrast with chemical synapse.)

electrocardiogram (ECG or EKG) A graphic recording of electrical potentials from the heart.

electrochemical gradient The concentration gradient of an ion across a membrane plus the voltage difference across that membrane.

electroencephalogram (EEG) A graphic recording of electrical potentials from the brain.

electromagnetic radiation A self-propagating wave that travels through space and has both electrical and magnetic properties.

electron A subatomic particle outside the nucleus carrying a negative charge and very little mass.

electron shell The region surrounding the atomic nucleus at a fixed energy level in which electrons orbit.

electron transport The passage of electrons through a series of proteins with a release of energy which may be captured in a concentration gradient or chemical form such as NADH or ATP.

electronegativity The tendency of an atom to attract electrons when it occurs as part of a compound.

electrophoresis *See* gel electrophoresis.

element A substance that cannot be converted to simpler substances by ordinary chemical means.

elongation (1) In molecular biology, the addition of monomers to make a longer RNA or protein during transcription or translation. (2) Growth of a plant axis or cell primarily in the longitudinal direction.

embolus (em’ buh lus) [Gk. *embolos*: stopper] A circulating blood clot. Blockage of a blood vessel by an embolus or by a bubble of gas is referred to as an *embolism*. (Contrast with thrombus.)

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as a seed, egg, or uterus.

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

embryo sac In angiosperms, the female gametophyte. Found within the ovule, it consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

emergent property A property of a complex system that is not exhibited by its individual component parts.

emigration The deliberate and usually oriented departure of an organism from the habitat in which it has been living.

3’ end (3 prime) The end of a DNA or RNA strand that has a free hydroxyl group at the 3’ carbon of the sugar (deoxyribose or ribose).

5’ end (5 prime) The end of a DNA or RNA strand that has a free phosphate group at the 5’ carbon of the sugar (deoxyribose or ribose).

endemic (en dem’ ik) [Gk. *endemos*: native] Confined to a particular region, thus often having a comparatively restricted distribution.

endergonic A chemical reaction in which the products have higher free energy than the reactants, thereby requiring free energy input to occur. (Contrast with exergonic.)

endocrine gland (en’ doh krin) [Gk. *endo*: within + *krinein*: to separate] An aggregation of secretory cells that secretes hormones into the blood. The *endocrine system* consists of all *endocrine cells* and endocrine glands in the body that produce and release hormones. (Contrast with exocrine gland.)

endocytosis A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

endodermis In plants, a specialized cell layer marking the inside of the cortex in roots and some stems. Frequently a barrier to free diffusion of solutes.

endomembrane system A system of intracellular membranes that exchange material with one another, consisting of the Golgi apparatus, endoplasmic reticulum, and lysosomes when present.

endometrium The epithelial lining of the uterus.

endoplasmic reticulum (ER) [Gk. *endo*: within + L. *reticulum*: net] A system of membranous tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists in two forms: rough ER,

studded with ribosomes; and smooth ER, lacking ribosomes.

endorphins Molecules in the mammalian brain act as neurotransmitters in pathways that control pain.

endoskeleton [Gk. *endo*: within + *skleros*: hard] An internal skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

endospore [Gk. *endo*: within + *spora*: to sow] In some bacteria, a resting structure that can survive harsh environmental conditions.

endosymbiosis theory [Gk. *endo*: within + *sym*: together + *bios*: life] The theory that the eukaryotic cell evolved via the engulfing of one prokaryotic cell by another.

endothelium The single layer of epithelial cells lining the interior of a blood vessel.

endotherm [Gk. *endo*: within + *thermos*: heat] An animal that can control its body temperature by the expenditure of its own metabolic energy. (Contrast with ectotherm.)

endotoxin A lipopolysaccharide that forms part of the outer membrane of certain Gram-negative bacteria that is released when the bacteria grow or lyse. (Contrast with exotoxin.)

energetic cost The difference between the energy an animal expends in performing a behavior and the energy it would have expended had it rested.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

energy budget A quantitative description of all paths of energy exchange between an animal and its environment.

enkephalins Molecules in the mammalian brain act as neurotransmitters in pathways that control pain.

enthalpy (H) The total energy of a system.

entropy (S) (en' tro pee) [Gk. *trophein*: to change] A measure of the degree of disorder in any system. Spontaneous reactions in a closed system are always accompanied by an increase in entropy.

enveloped virus A virus enclosed within a phospholipid membrane derived from its host cell.

environment Whatever surrounds and interacts with or otherwise affects a population, organism, or cell. May be external or internal.

environmentalism The use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy relating to stewardship of natural resources and ecosystems.

enzyme (en' zime) [Gk. *zyme*: to leaven (as in yeast bread)] A catalytic protein that speeds up a biochemical reaction.

epi- [Gk. upon, over] A prefix used to designate a structure located on top of another; for example, epidermis, epiphyte.

epiblast The upper or overlying portion of the avian blastula which is joined to the hypoblast at the margins of the blastodisc.

epiboly The movement of cells over the surface of the blastula toward the forming blastopore.

epitope See antigenic determinant.

epidermis [Gk. *epi*: over + *derma*: skin] In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

epididymis (epuh did' uh mus) [Gk. *epi*: over + *didymos*: testicle] Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

epigenetics The scientific study of changes in the expression of a gene or set of genes that occur without change in the DNA sequence.

epinephrine (ep i nef' rin) [Gk. *epi*: over + *nephros*: kidney] The "fight or flight" hormone produced by the medulla of the adrenal gland; it also functions as a neurotransmitter. (Also known as adrenaline.)

epistasis Interaction between genes in which the presence of a particular allele of one gene determines whether another gene will be expressed.

epithelium A type of animal tissue made up of sheets of cells that lines or covers organs, makes up tubules, and covers the surface of the body; one of the four major tissue types in multicellular animals.

equilibrium Any state of balanced opposing forces and no net change.

ER See endoplasmic reticulum.

error signal In regulatory systems, any difference between the set point of the system and its current condition.

erythrocyte (ur rith' row site) [Gk. *erythros*: red + *kytos*: container] A red blood cell.

erythropoietin A hormone produced by the kidney in response to lack of oxygen that stimulates the production of red blood cells.

esophagus (i soff' i gus) [Gk. *oisophagos*: gullet] That part of the gut between the pharynx and the stomach.

essential acids Amino acids or fatty acids that an animal cannot synthesize for itself and must obtain from its food.

essential element A mineral nutrient required for normal growth and reproduction in plants and animals.

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids are formed in this way.

estivation (ess tuh vay' shun) [L. *aestivalis*: summer] A state of dormancy and hypometabolism that occurs during the summer; usually a means of surviving drought and/or intense heat. (Contrast with hibernation.)

estrogen Any of several steroid sex hormones; produced chiefly by the ovaries in mammals.

estrus (es' trus) [L. *oestrus*: frenzy] The period of heat, or maximum sexual receptivity, in some female mammals. Ordinarily, the estrus is also the time of release of eggs in the female.

ethology [Gk. *ethos*: character + *logos*: study] An approach to the study of animal behavior that focuses on studying many species in natural environments and addresses questions about the evolution of behavior.

ethylene One of the plant growth hormones, the gas H₂C=CH₂. Involved in fruit ripening and other growth and developmental responses.

eukaryotes (yew car' ree oats) [Gk. *eu*: true + *karyon*: kernel or nucleus] Organisms whose cells contain their genetic material inside a nu-

cleus. Includes all life other than the viruses, archaea, and bacteria.

eusocial Pertaining to a social group that includes nonreproductive individuals, as in honey bees.

eutrophication (yoo trofe' ik ay' shun) [Gk. *eu*: truly + *trephein*: to flourish] The addition of nutrient materials to a body of water, resulting in changes in ecological processes and species composition therein.

evaporation The transition of water from the liquid to the gaseous phase.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution; contrast with speciation.)

evolutionary radiation The proliferation of many species within a single evolutionary lineage.

evolutionary reversal The reappearance of an ancestral trait in a group that had previously acquired a derived trait.

excision repair A mechanism that removes damaged DNA and replaces it with the appropriate nucleotide.

excited state The state of an atom or molecule when, after absorbing energy, it has more energy than in its normal, ground state. (Contrast with ground state.)

excretion Release of metabolic wastes by an organism.

exergonic A chemical reaction in which the products of the reaction have lower free energy than the reactants, resulting in a release of free energy. (Contrast with endergonic.)

exocrine gland (eks' oh krin) [Gk. *exo*: outside + *krinein*: to separate] Any gland, such as a salivary gland, that secretes to the outside of the body or into the gut. (Contrast with endocrine gland.)

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

exon A portion of a DNA molecule, in eukaryotes, that codes for part of a polypeptide. (Contrast with intron.)

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

exotoxin A highly toxic, usually soluble protein released by living, multiplying bacteria. (Contrast with endotoxin.)

expanding triplet repeat A three-base-pair sequence in a human gene that is unstable and can be repeated a few to hundreds of times. Often, the more the repeats, the less the activity of the gene involved. Expanding triplet repeats occur in some human diseases such as Huntington's disease and fragile-X syndrome.

experiment A testing process to support or disprove hypotheses and to answer questions. The basis of the scientific method. See comparative experiment, controlled experiment.

expiratory reserve volume The amount of air that can be forcefully exhaled beyond the normal tidal expiration. (Contrast with inspiratory reserve volume, tidal volume, vital capacity.)

exploitation competition Competition in which individuals reduce the quantities of their shared resources. (Contrast with interference competition.)

exponential growth Growth, especially in the number of organisms in a population, which is a geometric function of the size of the growing entity: the larger the entity, the faster it grows. (Contrast with logistic growth.)

expression vector A DNA vector, such as a plasmid, that carries a DNA sequence that includes the adjacent sequences for its expression into mRNA and protein in a host cell.

expressivity The degree to which a genotype is expressed in the phenotype; may be affected by the environment.

extensor A muscle that extends an appendage.

external fertilization The release of gametes into the environment; typical of aquatic animals. Also called spawning. (Contrast with internal fertilization.)

external gills Highly branched and folded extensions of the body surface that provide a large surface area for gas exchange with water; typical of larval amphibians and many larval insects.

extinction The termination of a lineage of organisms.

extracellular matrix A material of heterogeneous composition surrounding cells and performing many functions including adhesion of cells.

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups phylogenetically as amniotes. (See amnion, allantois, chorion, and yolk sac.)

- F -

F₁ The first filial generation; the immediate progeny of a parental (P) mating.

F₂ The second filial generation; the immediate progeny of a mating between members of the F₁ generation.

facilitated diffusion Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, diffusion.)

facilitation In succession, modification of the environment by a colonizing species in a way that allows colonization by other species. (Contrast with inhibition.)

facultative anaerobe A prokaryote that can shift its metabolism between anaerobic and aerobic operations modes on the presence or absence of O₂. (Alternatively, facultative aerobe.)

fast-twitch fibers Skeletal muscle fibers that can generate high tension rapidly, but fatigue rapidly ("sprinter" fibers). Characterized by an abundance of enzymes of glycolysis.

fat A triglyceride that is solid at room temperature. (Contrast with oil.)

fate map A diagram of the blastula showing which cells (blastomeres) are "fated" to contribute to specific tissues and organs in the mature body.

fatty acid A molecule made up of a long non-polar hydrocarbon chain and a polar carboxyl group. Found in many lipids.

fauna (faw' nah) All the animals found in a given area. (Contrast with flora.)

feces [L. *faeces*: dregs] Waste excreted from the digestive system.

fecundity (m_x) The average number of offspring produced by each female.

feedback information In regulatory systems, information about the relationship between the set point of the system and its current state.

feedforward information In regulatory systems, information that changes the set point of the system.

fermentation (fur men tay' shun) [L. *fermentum*: yeast] The anaerobic degradation of a substance such as glucose to smaller molecules such as lactic acid or alcohol with the extraction of energy.

fertilization Union of gametes. Also known as syngamy.

fetus Medical and legal term for the stages of a developing human embryo from about the eighth week of pregnancy (the point at which all major organ systems have formed) to the moment of birth.

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves as a support function in xylem. (See also muscle fiber.)

fibrin A protein that polymerizes to form long threads that provide structure to a blood clot.

fibrinogen A circulating protein that can be stimulated to fall out of solution and provide the structure for a blood clot.

fibrous root system A root system typical of monocots composed of numerous thin adventitious roots that are all roughly equal in diameter. (Contrast with taproot system.)

Fick's law of diffusion An equation that describes the factors that determine the rate of diffusion of a molecule from an area of higher concentration to an area of lower concentration.

fight-or-flight response A rapid physiological response to a sudden threat mediated by the hormone epinephrine.

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device.

first law of thermodynamics The principle that energy can be neither created nor destroyed.

fission See binary fission.

fitness The contribution of a genotype or phenotype to the genetic composition of subsequent generations, relative to the contribution of other genotypes or phenotypes. (See also inclusive fitness.)

flagellum (fla jell' um) (plural: flagella) [L. *flagellum*: whip] Long, whiplike appendage that propels cells. Prokaryotic flagella differ sharply from those found in eukaryotes.

fixed action pattern In ethology, a genetically determined behavior that is performed without learning, stereotypic (performed the same way each time), and not modifiable by learning.

flexor A muscle that flexes an appendage.

flora (flor' ah) All of the plants found in a given area. (Contrast with fauna.)

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

floral organ identity genes In angiosperms, genes that determine the fates of floral meristem cells; their expression is triggered by the products of meristem identity genes.

florigen A plant hormone involved in the conversion of a vegetative shoot apex to a flower.

flower The sexual structure of an angiosperm.

fluid feeder An animal that feeds on fluids it extracts from the bodies of other organisms; examples include nectar-feeding birds and blood-sucking insects.

fluid mosaic model A molecular model for the structure of biological membranes consisting of a fluid phospholipid bilayer in which suspended proteins are free to move in the plane of the bilayer.

follicle [L. *folliculus*: little bag] In female mammals, an immature egg surrounded by nutritive cells.

follicle-stimulating hormone (FSH) A gonadotropin produced by the anterior pituitary.

food chain A portion of a food web, most commonly a simple sequence of prey species and the predators that consume them.

food vacuole Membrane enclosed structure formed by phagocytosis in which engulfed food particles are digested by the action of lysosomal enzymes.

food web The complete set of food links between species in a community; a diagram indicating which ones are the eaters and which are eaten.

forebrain The region of the vertebrate brain that comprises the cerebrum, thalamus, and hypothalamus.

fossil Any recognizable structure originating from an organism, or any impression from such a structure, that has been preserved over geological time.

fossil fuels Fuels, including oil, natural gas, coal, and peat, formed over geologic time from organic material buried in anaerobic sediments.

founder effect Random changes in allele frequencies resulting from establishment of a population by a very small number of individuals.

fovea [L. *fovea*: a small pit] In the vertebrate retina, the area of most distinct vision.

frame-shift mutation The addition or deletion of a single or two adjacent nucleotides in a gene's sequence. Results in the misreading of mRNA during translation and the production of a non-functional protein. (Contrast with missense mutation, nonsense mutation, silent mutation.)

Frank-Starling law The stroke volume of the heart increases with increased return of blood to the heart.

free energy (G) Energy that is available for doing useful work, after allowance has been made for the increase or decrease of disorder.

freeze-fracturing Method of tissue preparation for transmission and scanning electron microscopy in which a tissue is frozen and a knife is then used to crack open the tissue; the fracture often occurs in the path of least resistance, within a membrane.

frequency-dependent selection Selection that changes in intensity with the proportion of individuals in a population having the trait.

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

functional genomics The assignment of functional roles to the proteins encoded by genes identified by sequencing entire genomes.

functional group A characteristic combination of atoms that contribute specific properties when attached to larger molecules.

fundamental niche A species' niche as defined by its physiological capabilities. (Contrast with realized niche.)

- G -

G cap A chemically modified GTP added to the 5' end of mRNA; facilitates binding of mRNA to ribosome and prevents mRNA breakdown.

G1 In the cell cycle, the gap between the end of mitosis and the onset of the S phase.

G2 In the cell cycle, the gap between the S (synthesis) phase and the onset of mitosis.

G protein A membrane protein involved in signal transduction; characterized by binding GDP or GTP.

gain of function mutation A mutation that results in a protein with a new function. (Contrast with loss of function mutation.)

gallbladder In the human digestive system, an organ in which bile is stored.

gametangium (gam uh tan' gee um) (plural: gametangia) [Gk. *gamos*: marriage + *angeion*: vessel] Any plant or fungal structure within which a gamete is formed.

gamete (gam' eet) [Gk. *gamete*/ *gametes*: wife, husband] The mature sexual reproductive cell: the egg or the sperm.

gametogenesis (ga meet' oh jen' e sis) The specialized series of cellular divisions that leads to the production of gametes. (See also oogenesis, spermatogenesis.)

gametophyte (ga meet' oh fyte) In plants and photosynthetic protists with alternation of generations, the multicellular haploid phase that produces the gametes. (Contrast with sporophyte.)

gamma diversity The regional diversity found over a range of communities or habitats in a geographic region. (Contrast with alpha diversity, beta diversity.)

ganglion (gang' glee un) (plural: ganglia) [Gk. tumor] A cluster of neurons that have similar characteristics or function.

ganglion cells Cells at the front of the human retina that transmit information from the bipolar cells to the brain.

gap junction A 2.7-nanometer gap between plasma membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

gastric pits Deep infoldings in the walls of the stomach lined with secretory cells.

gastrin A hormone secreted by cells in the lower region of the stomach that stimulates the secretion of digestive juices as well as movements of the stomach.

gastrovascular cavity Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

gastrulation Development of a blastula into a gastrula. In embryonic development, the process by which a blastula is transformed by massive movements of cells into a *gastrula*, an embryo with three germ layers and distinct body axes.

gated channel A membrane protein that changes its three-dimensional shape, and therefore its ion conductance, in response to a stimulus. When open, it allows specific ions to move across the membrane.

gel electrophoresis (e lek' tro fo ree' sis) [L. *electrum*: amber + Gk. *phorein*: to bear] A technique

for separating molecules (such as DNA fragments) from one another on the basis of their electric charges and molecular weights by applying an electric field to a gel.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a single polypeptide or RNA.

gene family A set of similar genes derived from a single parent gene; need not be on the same chromosomes. The vertebrate globin genes constitute a classic example of a gene family.

gene flow Exchange of genes between populations through migration of individuals or movements of gametes.

gene-for-gene resistance In plants, a mechanism of resistance to pathogens in which resistance is triggered by the specific interaction of the products of a pathogen's *Avr* genes and a plant's *R* genes.

gene pool All of the different alleles of all of the genes existing in all individuals of a population.

gene therapy Treatment of a genetic disease by providing patients with cells containing functioning alleles of the genes that are nonfunctional in their bodies.

gene tree A graphic representation of the evolutionary relationships of a single gene in different species or of the members of a gene family.

genetic code The set of instructions, in the form of nucleotide triplets, that translate a linear sequence of nucleotides in mRNA into a linear sequence of amino acids in a protein.

genetic drift Changes in gene frequencies from generation to generation as a result of random (chance) processes.

genetic map The positions of genes along a chromosome as revealed by recombination frequencies.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated with the presence of other linked genes on that chromosome.

genetic structure The frequencies of different alleles at each locus and the frequencies of different genotypes in a Mendelian population.

genetic switches Mechanisms that control how the genetic toolkit is used, such as promoters and the transcription factors that bind them. The signal cascades that converge on and operate these switches determine when and where genes will be turned on and off.

genetic toolkit In evolutionary developmental biology, DNA sequences controlling developmental mechanisms that have been conserved over evolutionary time.

genetics The scientific study of the structure, functioning, and inheritance of genes, the units of hereditary information.

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

genomic equivalence The principle that no information is lost from the nuclei of cells as they pass through the early stages of embryonic development.

genomic imprinting The form of a gene's expression is determined by parental source (i.e.,

whether the gene is inherited from the male or female parent).

genomic library All of the cloned DNA fragments generated by the action of a restriction endonuclease on a genome.

genomics The scientific study of entire sets of genes and their interactions.

genotype (jean' oh type) [Gk. *gen*: to produce + *typos*: impression] An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

genus (jean' us) (plural: genera) [Gk. *genos*: stock, kind] A group of related, similar species recognized by taxonomists with a distinct name used in binomial nomenclature.

germ cell [L. *germen*: to beget] A reproductive cell or gamete of a multicellular organism. (Contrast with somatic cell.)

germ layers The three embryonic layers formed during gastrulation (ectoderm, mesoderm, and endoderm). Also called cell layers or tissue layers.

germ line mutation Mutation in a cell that produces gametes (i.e., a germ line cell). (Contrast with somatic mutation.)

germination Sprouting of a seed or spore.

gestation (jes tay' shun) [L. *gestare*: to bear] The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

ghrelin A hormone produced and secreted by cells in the stomach that stimulates appetite.

gibberellin (jib er el' lin) A class of plant growth hormones playing roles in stem elongation, seed germination, flowering of certain plants, etc.

gill An organ specialized for gas exchange with water.

gizzard (giz' erd) [L. *gigeria*: cooked chicken parts] A muscular part of the stomach of birds that grinds up food, sometimes with the aid of fragments of stone.

glia (glee' uh) [Gk. *glia*: glue] Cells of the nervous system that do not conduct action potentials.

glomerular filtration rate (GFR) The rate at which the blood is filtered in the glomeruli of the kidney.

glomerulus (glo mare' yew lus) [L. *glomus*: ball] Sites in the kidney where blood filtration takes place. Each glomerulus consists of a knot of capillaries served by afferent and efferent arterioles.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

gluconeogenesis The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

glucose [Gk. *gleukos*: sugar, sweet] The most common monosaccharide; the monomer of the polysaccharides starch, glycogen, and cellulose.

glycerol (gliss' er ole) A three-carbon alcohol with three hydroxyl groups; a component of phospholipids and triglycerides.

glycogen (gly' ko jen) An energy storage polysaccharide found in animals and fungi; a branched-chain polymer of glucose, similar to starch.

glycolipid A lipid to which sugars are attached.

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

glycoprotein A protein to which sugars are attached.

glycosidic linkage Bond between carbohydrate (sugar) molecules through an intervening oxygen atom (–O–).

glycosylation The addition of carbohydrates to another type of molecule, such as a protein.

glyoxysome (gly ox' ee soam) An organelle found in plants, in which stored lipids are converted to carbohydrates.

Golgi apparatus (goal' jee) A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells; functions in secretion from cell by exocytosis.

gonad (go' nad) [Gk. *gone*: seed] An organ that produces gametes in animals: either an ovary (female gonad) or testis (male gonad).

gonadotropin A type of trophic hormone that stimulates the gonads.

gonadotropin-releasing hormone (GnRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to secrete ("release") gonadotropins.

Gondwana The large southern land mass that existed from the Cambrian (540 mya) to the Jurassic (138 mya). Present-day remnants are South America, Africa, India, Australia, and Antarctica.

grafting Artificial transplantation of tissue from one organism to another. In horticulture, the transfer of a bud or stem segment from one plant onto the root of another as a form of asexual reproduction.

Gram stain A differential purple stain useful in characterizing bacteria. The peptidoglycan-rich cell walls of Gram-positive bacteria stain purple; cell walls of Gram-negative bacteria generally stain orange.

gravitropism [Gk. *tropos*: to turn] A directed plant growth response to gravity.

gray matter In the nervous system, tissue that is rich in neuronal cell bodies. (Contrast with white matter.)

greenhouse gases Gases in the atmosphere, such as carbon dioxide and methane, that are transparent to sunlight, but trap heat radiating from Earth's surface, causing heat to build up at Earth's surface.

gross primary production The amount of energy captured by the primary producers in a community.

gross primary productivity (GPP) The rate at which the primary producers in a community turn solar energy into stored chemical energy via photosynthesis.

ground meristem That part of an apical meristem that gives rise to the ground tissue system of the primary plant body.

ground tissue system Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

growth An increase in the size of the body and its organs by cell division and cell expansion.

growth factor A chemical signal that stimulates cells to divide.

growth hormone A peptide hormone released by the anterior pituitary that stimulates many anabolic processes.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

guard cells In plants, specialized, paired epidermal cells that surround and control the opening of a stoma (pore). *See* stoma.

guild In ecology, a group of species that exploit the same resource, but in slightly different ways.

gustation The sense of taste.

gut An animal's digestive tract.

- H -

habitat The particular environment in which an organism lives. A *habitat patch* is an area of a particular habitat surrounded by other habitat types that may be less suitable for that organism.

hair cell A type of mechanoreceptor in animals. Detects sound waves and other forms of motion in air or water.

half-life The time required for half of a sample of a radioactive isotope to decay to its stable, nonradioactive form, or for a drug or other substance to reach half its initial dosage.

halophyte (hal' oh fyte) [Gk. *halos*: salt + *phyton*: plant] A plant that grows in a saline (salty) environment.

Hamilton's rule The principle that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness of the performer and the recipient must be greater than the cost to the performer.

haplodiploidy A sex determination mechanism in which diploid individuals (which develop from fertilized eggs) are female and haploid individuals (which develop from unfertilized eggs) are male; typical of hymenopterans.

haploid (hap' loid) [Gk. *haploides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated *1n* or *n*. (Contrast with diploid.)

haplontic A type of life cycle in which the zygote is the only diploid cell and mitosis occurs only in haploid cells. (Contrast with diplontic.)

haplotype Linked nucleotide sequences that are usually inherited as a unit (as a "sentence" rather than as individual "words").

Hardy-Weinberg equilibrium In a sexually reproducing population, the allele frequency at a given locus that is not being acted on by agents of evolution; the conditions that would result in no evolution in a population.

haustorium (haw stor' ee um) (plural: haustoria) [L. *haustus*: draw up] A specialized hypha or other structure by which fungi and some parasitic plants draw nutrients from a host plant.

Haversian systems Units of organization in compact bone that reflect the action of intercommunicating osteoblasts.

heart In circulatory systems, a muscular pump that moves extracellular fluid around the body.

heat of vaporization The energy that must be supplied to convert a molecule from a liquid to a gas at its boiling point.

heat shock proteins Chaperone proteins expressed in cells exposed to high or low temperatures or other forms of environmental stress.

helical Shaped like a screw or spring; this shape occurs in DNA and proteins.

helper T cells *See* T-helper cells.

hemiparasite A parasitic plant that can photosynthesize, but derives water and mineral nutrients from the living body of another plant. (Contrast with holoparasite.)

hemizygous (hem' ee zie' gus) [Gk. *hemi*: half + *zygotos*: joined] In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

hemoglobin (hee' mo glow bin) [Gk. *heama*: blood + L. *globus*: globe] Oxygen-transporting protein found in the red blood cells of vertebrates (and found in some invertebrates).

Hensen's node In avian embryos, a structure at the anterior end of the primitive groove; determines the fates of cells passing over it during gastrulation.

hepatic (heh pat' ik) [Gk. *hepar*: liver] Pertaining to the liver.

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

heritable trait A trait that is at least partly determined by genes.

hermaphroditism (her maf' row dite ism) The coexistence of both female and male sex organs in the same organism.

hetero- [Gk.: *heteros*: other, different] A prefix indicating two or more different conditions, structures, or processes. (Contrast with homo-.)

heterochrony Alteration in the timing of developmental events, leading to different results in the adult organism.

heterocyst A large, thick-walled cell type in the filaments of certain cyanobacteria that performs nitrogen fixation.

heteromorphic (het' er oh more' fik) [Gk. *heteros*: different + *morphe*: form] Having a different form or appearance, as two heteromorphic life stages of a plant. (Contrast with isomorphic.)

heterosporous (het' er os' por us) Producing two types of spores, one of which gives rise to a female megaspore and the other to a male microspore. (Contrast with homosporous.)

heterosis The superior fitness of heterozygous offspring as compared with that of their dissimilar homozygous parents. Also called hybrid vigor.

heterotherm An animal that regulates its body temperature at a constant level at some times but not others, such as a hibernator.

heterotroph (het' er oh trof) [Gk. *heteros*: different + *trophe*: feed] An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

heterotrophic succession Succession in detritus-based communities, which differs from other types of succession in taking place without the participation of plants.

heterotypic Pertaining to adhesion of cells of different types. (Contrast with homotypic.)

heterozygous (het' er oh zie' gus) [Gk. *heteros*: different + *zygotos*: joined] In diploid organisms, having different alleles of a given gene on the pair of homologs carrying that gene. (Contrast with homozygous.)

hexose [Gk. *hex*: six] A sugar containing six carbon atoms.

hibernation [L. *hibernum*: winter] The state of inactivity of some animals during winter; marked by a drop in body temperature and metabolic rate.

hierarchical sequencing An approach to DNA sequencing in which genetic markers are mapped and DNA sequences are aligned by matching overlapping sites of known sequence. (Contrast with shotgun sequencing.)

high-density lipoproteins (HDLs) Lipoproteins that remove cholesterol from tissues and carry it to the liver; HDLs are the “good” lipoproteins associated with good cardiovascular health.

high-throughput sequencing Rapid DNA sequencing on a micro scale in which many fragments of DNA are sequenced in parallel.

highly repetitive sequences Short (less than 100 bp), nontranscribed DNA sequences, repeated thousands of times in tandem arrangements.

hindbrain The region of the developing vertebrate brain that gives rise to the medulla, pons, and cerebellum.

hippocampus [Gr. sea horse] A part of the forebrain that takes part in long-term memory formation.

histamine (hiss’ tah meen) A substance released by damaged tissue, or by mast cells in response to allergens. Histamine increases vascular permeability, leading to edema (swelling).

histone Any one of a group of proteins forming the core of a nucleosome, the structural unit of a eukaryotic chromosome.

HIV Human immunodeficiency virus, the retrovirus that causes acquired immune deficiency syndrome (AIDS).

holoparasite A fully parasitic plant (i.e., one that does not perform photosynthesis).

homeobox 180-base-pair segment of DNA found in certain homeotic genes; regulates the expression of other genes and thus controls large-scale developmental processes.

homeostasis (home’ ee o sta’ sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature or a stable social structure, by means of physiological or behavioral feedback responses.

homeotic genes Genes that act during development to determine the formation of an organ from a region of the embryo.

homeotic mutation Mutation in a homeotic gene that results in the formation of a different organ than that normally made by a region of the embryo.

homo- [Gk. *homos*: same] A prefix indicating two or more similar conditions, structures, or processes. (Contrast with hetero-.)

homolog (1) In cytogenetics, one of a pair (or larger set) of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent. (2) In evolutionary biology, one of two or more features in different species that are similar by reason of descent from a common ancestor.

homology (ho mol’ o jee) [Gk. *homologia*: of one mind; agreement] A similarity between two or more features that is due to inheritance from a common ancestor. The structures are said to be *homologous*, and each is a *homolog* of the others. (Contrast with analogy.)

homoplasmy (home’ uh play zee) [Gk. *homos*: same + *plastikos*: shape, mold] The presence in multiple groups of a trait that is not inherited from the common ancestor of those groups. Can result from convergent evolution, evolutionary reversal, or parallel evolution.

homosporous Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterosporous.)

homotypic Pertaining to adhesion of cells of the same type. (Contrast with heterotypic.)

homozygous (home’ oh zie’ gus) [Gk. *homos*: same + *zygotos*: joined] In diploid organisms, having identical alleles of a given gene on both homologous chromosomes. An individual may be a homozygote with respect to one gene and a heterozygote with respect to another. (Contrast with heterozygous.)

horizons The horizontal layers of a soil profile, including the topsoil (A horizon), subsoil (B horizon) and parent rock or bedrock (C horizon)

hormone (hore’ mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

host An organism that harbors a parasite or symbiont and provides it with nourishment.

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal groups. Hox genes contain the homeobox domain and specify pattern and axis formation in these animals.

human chorionic gonadotropin (hCG) A hormone secreted by the placenta which sustains the corpus luteum and helps maintain pregnancy.

humoral immune response The response of the immune system mediated by B cells that produces circulating antibodies active against extracellular bacterial and viral infections. (Contrast with cellular immune response.)

humus (hew’ mus) The partly decomposed remains of plants and animals on the surface of a soil.

hybrid (high’ brid) [L. *hybrida*: mongrel] (1) The offspring of genetically dissimilar parents. (2) In molecular biology, a double helix formed of nucleic acids from different sources.

hybridize (1) In genetics, to combine the genetic material of two distinct species or of two distinguishable populations within a species. (2) In molecular biology, to form a double-stranded nucleic acid in which the two strands originate from different sources.

hybrid vigor See heterosis.

hybridoma A cell produced by the fusion of an antibody-producing cell with a myeloma (tumor) cell; it produces monoclonal antibodies.

hydrocarbon A compound containing only carbon and hydrogen atoms.

hydrogen bond A weak electrostatic bond which arises from the attraction between the slight positive charge on a hydrogen atom and a slight negative charge on a nearby oxygen or nitrogen atom.

hydrologic cycle The movement of water from the oceans to the atmosphere, to the soil, and back to the oceans.

hydrolysis reaction (high drol’ uh sis) [Gk. *hydro*: water + *lysis*: break apart] A chemical reaction that breaks a bond by inserting the components

of water ($AB + H_2O \rightarrow AH + BOH$). (Contrast with condensation reaction.)

hydrophilic (high dro fil’ ik) [Gk. *hydro*: water + *philia*: love] Having an affinity for water. (Contrast with hydrophobic.)

hydrophobic (high dro foe’ bik) [Gk. *hydro*: water + *phobia*: fear] Having no affinity for water. Uncharged and nonpolar groups of atoms are hydrophobic. (Contrast with hydrophilic.)

hydroponic Pertaining to a method of growing plants with their roots suspended in nutrient solutions instead of soil.

hydrostatic pressure Pressure generated by compression of liquid in a confined space. Generated in plants, fungi, and some protists with cell walls by the osmotic uptake of water. Generated in animals with closed circulatory systems by the beating of a heart.

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

hydroxyl group The —OH group found on alcohols and sugars.

hyper- [Gk. *hyper*: above, over] Prefix indicating above, higher, more. (Contrast with hypo-.)

hyperpolarization A change in the resting potential across a membrane so that the inside of a cell becomes more negative compared with the outside of the cell. (Contrast with depolarization.)

hypersensitive response A defensive response of plants to microbial infection in which phytoalexins and pathogenesis-related proteins are produced and the infected tissue undergoes apoptosis to isolate the pathogen from the rest of the plant.

hypertonic Having a greater solute concentration. Said of one solution compared with another. (Contrast with hypotonic, isotonic.)

hypha (high’ fuh) (plural: hyphae) [Gk. *hyphē*: web] In the fungi and oomycetes, any single filament.

hypo- [Gk. *hypo*: beneath, under] Prefix indicating underneath, below, less. (Contrast with hyper-.)

hypoblast The lower tissue portion of the avian blastula which is joined to the epiblast at the margins of the blastodisc.

hypothalamus The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

hypothermia Below-normal body temperature.

hypothesis A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

hypotonic Having a lesser solute concentration. Said of one solution in comparing it to another. (Contrast with hypertonic, isotonic.)

hypoxia A deficiency of oxygen.

- I -

ileum The final segment of the small intestine.

imbibition Water uptake by a seed; first step in germination.

immediate hypersensitivity A rapid, extensive overreaction of the immune system against an allergen, resulting in the release of large amounts of histamine. (Contrast with delayed hypersensitivity.)

immediate memory A form of memory for events happening in the present that is almost

perfectly photographic, but lasts only seconds. (Contrast with short-term memory, long-term memory.)

immune system [L. *immunis*: exempt from] A system in an animal that recognizes and attempts to eliminate or neutralize foreign substances such as bacteria, viruses, and pollutants.

immunoassay The use of antibodies to measure the concentration of an antigen in a sample.

immunoglobulins A class of proteins containing a tetramer consisting of four polypeptide chains—two identical light chains and two identical heavy chains—held together by disulfide bonds; active as receptors and effectors in the immune system.

immunological memory The capacity to more rapidly and massively respond to a second exposure to an antigen than occurred on first exposure.

imperfect flower A flower lacking either functional stamens or functional carpels. (Contrast with perfect flower.)

implantation The process by which the early mammalian embryo becomes attached to and embedded in the lining of the uterus.

imprinting In animal behavior, a rapid form of learning in which an animal learns, during a brief critical period, to make a particular response, which is maintained for life, to some object or other organism. *See also* genomic imprinting.

in vitro [L. in glass] A biological process occurring outside of the organism, in the laboratory. (Contrast with *in vivo*.)

in vivo [L. alive] A biological process occurring within a living organism or cell. (Contrast with *in vitro*.)

inbreeding Breeding among close relatives.

inclusive fitness The sum of an individual's genetic contribution to subsequent generations both via production of its own offspring and via its influence on the survival of relatives who are not direct descendants.

incomplete cleavage A pattern of cleavage that occurs in many eggs that have a lot of yolk, in which the cleavage furrows do not penetrate all of it. (*See also* discoidal cleavage, superficial cleavage; contrast with complete cleavage.)

incomplete dominance Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

incomplete metamorphosis Insect development in which changes between instars are gradual.

independent assortment During meiosis, the random separation of genes carried on nonhomologous chromosomes into gametes so that inheritance of these genes is random. This principle was articulated by Mendel as his second law.

indeterminate growth A open-ended growth pattern in which an organism or organ continues to grow as long as it lives; characteristic of some animals and of plant shoots and roots. (Contrast with determinate growth.)

indirect transduction Cell signaling mechanism in which a second messenger mediates the interaction between receptor binding and cellular response. (Contrast with direct transduction.)

individual fitness That component of inclusive fitness resulting from an organism producing its own offspring. (Contrast with kin selection.)

induced fit A change in the shape of an enzyme caused by binding to its substrate that exposes the active site of the enzyme.

induced mutation A mutation resulting from exposure to a mutagen from outside the cell. (Contrast with spontaneous mutation.)

induced pluripotent stem cells (iPS cells) Multipotent or pluripotent animal stem cells produced from differentiated cells *in vitro* by the addition of several genes that are expressed.

inducer (1) A compound that stimulates the synthesis of a protein. (2) In embryonic development, a substance that causes a group of target cells to differentiate in a particular way.

inducible Produced only in the presence of a particular compound or under particular circumstances. (Contrast with constitutive.)

induction In embryonic development, the process by which a factor produced and secreted by certain cells determines the fates of other cells.

inflammation A nonspecific defense against pathogens; characterized by redness, swelling, pain, and increased temperature.

inflorescence A structure composed of several to many flowers.

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

ingroup In a phylogenetic study, the group of organisms of primary interest. (Contrast with outgroup.)

inhibitor A substance that blocks a biological process.

initials Cells that perpetuate plant meristems, comparable to animal stem cells. When an initial divides, one daughter cell develops into another initial, while the other differentiates into a more specialized cell.

initiation In molecular biology, the beginning of transcription or translation.

initiation complex In protein translation, a combination of a small ribosomal subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

initiation site The part of a promoter where transcription begins.

inner cell mass Derived from the mammalian blastula (blastocyst), the inner cell mass will give rise to the yolk sac (via hypoblast) and embryo (via epiblast).

inositol triphosphate (IP₃) An intracellular second messenger derived from membrane phospholipids.

inspiratory reserve volume The amount of air that can be inhaled above the normal tidal inspiration. (Contrast with expiratory reserve volume, tidal volume, vital capacity.)

instar (in' star) An immature stage of an insect between molts.

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

integrin In animals, a transmembrane protein that mediates the attachment of epithelial cells to the extracellular matrix.

integument [L. *integumentum*: covering] A protective surface structure. In gymnosperms and angiosperms, a layer of tissue around the ovule which will become the seed coat.

intercostal muscles Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

interference competition Competition in which individuals actively interfere with one another's access to resources. (Contrast with exploitation competition.)

interference RNA (RNAi) *See* RNA interference.

interferon A glycoprotein produced by virus-infected animal cells; increases the resistance of neighboring cells to the virus.

intermediate filaments Components of the cytoskeleton whose diameters fall between those of the larger microtubules and those of the smaller microfilaments.

internal environment In multicellular organisms, the extracellular fluid surrounding the cells.

internal fertilization The release of sperm into the female reproductive tract; typical of most terrestrial animals. (Contrast with external fertilization.)

internal gills Gills enclosed in protective body cavities; typical of mollusks, arthropods, and fishes.

interneuron A neuron that communicates information between two other neurons.

internode The region between two nodes of a plant stem.

interphase In the cell cycle, the period between successive nuclear divisions during which the chromosomes are diffuse and the nuclear envelope is intact. During interphase the cell is most active in transcribing and translating genetic information.

interspecific competition Competition between members of two or more species. (Contrast with intraspecific competition.)

interstitial fluid Extracellular fluid that is not contained in the vessels of a circulatory system.

intestine The portion of the gut following the stomach, in which most digestion and absorption occurs.

intraspecific competition Competition among members of the same species. (Contrast with interspecific competition.)

intrinsic rate of increase (*r*) The rate at which a population can grow when its density is low and environmental conditions are highly favorable.

intron Portion of a gene within the coding region that is transcribed into pre-mRNA but is spliced out prior to translation. (Contrast with exon.)

invasive species An exotic species that reproduces rapidly, spreads widely, and has negative effects on the native species of the region to which it has been introduced.

invasiveness The ability of a pathogen to multiply in a host's body. (Contrast with toxicity.)

inversion A rare 180° reversal of the order of genes within a segment of a chromosome.

ion (eye' on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

ionic bond An electrostatic attraction between positively and negatively charged ions.

ionotropic receptors A receptor that that directly alters membrane permeability to a type of ion when it combines with its ligand.

iris (eye' ris) [Gk. *iris*: rainbow] The round, pigmented membrane that surrounds the pupil of the eye and adjusts its aperture to regulate the amount of light entering the eye.

island biogeography A theory proposing that the number of species on an island (or in another geographically defined and isolated area) represents a balance, or equilibrium, between the rate at which species immigrate to the island and the rate at which resident species go extinct.

islets of Langerhans Clusters of hormone-producing cells in the pancreas.

iso- [Gk. *iso*: equal] Prefix used for two separate entities that share some element of identity.

isogamous Having male and female gametes that are morphologically identical. (Contrast with anisogamous.)

isomers Molecules consisting of the same numbers and kinds of atoms, but differing in the bonding patterns by which the atoms are held together.

isomorphic (eye so more' fik) [Gk. *isos*: equal + *morphe*: form] Having the same form or appearance, as when the haploid and diploid life stages of an organism appear identical. (Contrast with heteromorphic.)

isotonic Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

isotope (eye' so tope) [Gk. *isos*: equal + *topos*: place] Isotopes of a given chemical element have the same number of protons in their nuclei (and thus are in the same position on the periodic table), but differ in the number of neutrons.

isozymes Enzymes of an organism that have somewhat different amino acid sequences but catalyze the same reaction.

iteroparous [L. *itero*, to repeat + *pario*, to beget] Reproducing multiple times in a lifetime. (Contrast with semelparous.)

- J -

jejunum (jih jew' num) The middle division of the small intestine, where most absorption of nutrients occurs. (See duodenum, ileum.)

jelly coat The outer protective layer of a sea urchin egg, which triggers an acrosomal reaction in sperm.

joint In skeletal systems, a junction between two or more bones.

juvenile hormone In insects, a hormone maintaining larval growth and preventing maturation or pupation.

- K -

K-strategist A species whose life history strategy allows it to persist at or near the carrying capacity (*K*) of its environment. (Contrast with *r*-strategist.)

karyogamy The fusion of nuclei of two cells. (Contrast with plasmogamy.)

karyotype The number, forms, and types of chromosomes in a cell.

keystone species Species that have a dominant influence on the composition of a community.

kidneys A pair of excretory organs in vertebrates.

kin selection That component of inclusive fitness resulting from helping the survival of rela-

tives containing the same alleles by descent from a common ancestor. (Contrast with individual fitness.)

kinase See protein kinase.

kinetic energy (kuh-net' ik) [Gk. *kinetos*: moving] The energy associated with movement. (Contrast with potential energy.)

kinetochore (kuh net' oh core) Specialized structure on a centromere to which microtubules attach.

knockout A molecular genetic method in which a single gene of an organism is permanently inactivated.

Koch's postulates A set of rules for establishing that a particular microorganism causes a particular disease.

Krebs cycle See citric acid cycle.

- L -

lagging strand In DNA replication, the daughter strand that is synthesized in discontinuous stretches. (See Okazaki fragments.)

larva (plural: larvae) [L. *lares*: guiding spirits] An immature stage of any animal that differs dramatically in appearance from the adult.

lateral [L. *latus*: side] Pertaining to the side.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

lateral line A sensory system in fishes consisting of a canal filled with water and hair cells running down each side under the surface of the skin, which senses disturbances in the surrounding water.

lateral meristem Either of the two meristems, the vascular cambium and the cork cambium, that give rise to a plant's secondary growth.

lateral root A root extending outward from the taproot in a taproot system; typical of eudicots.

laticifers (luh tiss' uh furs) In some plants, elongated cells containing secondary plant products such as latex.

Laurasia The northernmost of the two large continents produced by the breakup of Pangaea.

laws of thermodynamics [Gk. *thermos*: heat + *dynamis*: power] Laws derived from studies of the physical properties of energy and the ways energy interacts with matter. (See also first law of thermodynamics, second law of thermodynamics.)

leaching In soils, a process by which mineral nutrients in upper soil horizons are dissolved in water and carried to deeper horizons, where they are unavailable to plant roots.

leading strand In DNA replication, the daughter strand that is synthesized continuously. (Contrast with lagging strand.)

leaf (plural: leaves) In plants, the chief organ of photosynthesis.

leaf primordium (plural: primordia) An outgrowth on the side of the shoot apical meristem that will eventually develop into a leaf.

leghemoglobin In nitrogen-fixing plants, an oxygen-carrying protein in the cytoplasm of nodule cells that transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

lek A display ground within which male animals compete for and defend small display areas as a means of demonstrating their territorial prowess and winning opportunities to mate.

lens In the vertebrate eye, a crystalline protein structure that makes fine adjustments in the focus of images falling on the retina.

lenticel (len' ti sill) In plants, a spongy region in the periderm that allows gas exchange.

leptin A hormone produced by fat cells that is believed to provide feedback information to the brain about the status of the body's fat reserves.

leukocyte See white blood cell.

lichen (lie' kun) An organism resulting from the symbiotic association of a fungus and either a cyanobacterium or a unicellular alga.

life cycle The entire span of the life of an organism from the moment of fertilization (or asexual generation) to the time it reproduces in turn.

life history strategy The way in which an organism partitions its time and energy among growth, maintenance, and reproduction.

ligament A band of connective tissue linking two bones in a joint.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

light reactions The initial phase of photosynthesis, in which light energy is converted into chemical energy.

light-independent reactions The phase of photosynthesis in which chemical energy captured in the light reactions is used to drive the reduction of CO₂ to form carbohydrates.

lignin A complex, hydrophobic polyphenolic polymer in plant cell walls that crosslinks other wall polymers, strengthening the walls, especially in wood.

limbic system A group of evolutionarily primitive structures in the vertebrate telencephalon that are involved in emotions, drives, instinctive behaviors, learning, and memory.

liming Application of compounds such as calcium carbonate, calcium hydroxide, or magnesium carbonate—commonly known as *lime*—to soil to reverse its acidification and increase the availability of calcium to plants.

limiting resource The required resource whose supply most strongly influences the size of a population.

lineage species concept The definition of a species as a branch on the tree of life, which has a history that starts at a speciation event and ends either at extinction or at another speciation event. (Contrast with biological species concept; morphological species concept.)

linkage Association between genes on the same chromosome such that they do not show random assortment and seldom recombine; the closer the genes, the lower the frequency of recombination.

lipase (lip' ase; lye' pase) An enzyme that digests fats.

lipid (lip' id) [Gk. *lipos*: fat] Nonpolar, hydrophobic molecules that include fats, oils, waxes, steroids, and the phospholipids that make up biological membranes.

lipid bilayer See phospholipid bilayer.

liver A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

loam A type of soil consisting of a mixture of sand, silt, clay, and organic matter. One of the best soil types for agriculture.

locus (low' kus) (plural: loci, low' sigh) In genetics, a specific location on a chromosome. May be considered synonymous with *gene*.

logistic growth Growth, especially in the size of an organism or in the number of organisms in a population, that slows steadily as the entity approaches its maximum size. (Contrast with exponential growth.)

long-day plant (LDP) A plant that requires long days (actually, short nights) in order to flower.

long-term depression (LTD) A long-lasting decrease in the responsiveness resulting from continuous, repetitive, low-level stimulation. (Contrast with long-term potentiation.)

long-term potentiation (LTP) A long-lasting increase in the responsiveness of a neuron resulting from a period of intense stimulation. (Contrast with long-term depression.)

loop of Henle (hen' lee) Long, hairpin loop of the mammalian renal tubule that runs from the cortex down into the medulla and back to the cortex; creates a concentration gradient in the interstitial fluids in the medulla.

lophophore A U-shaped fold of the body wall with hollow, ciliated tentacles that encircles the mouth of animals in several different groups. Used for filtering prey from the surrounding water.

loss of function mutation A mutation that results in the loss of a functional protein. (Contrast with gain of function mutation.)

low-density lipoproteins (LDLs) Lipoproteins that transport cholesterol around the body for use in biosynthesis and for storage; LDLs are the "bad" lipoproteins associated with a high risk of cardiovascular disease.

lumen (loo' men) [L. *lumen*: light] The open cavity inside any tubular organ or structure, such as the gut or a renal tubule.

lung An internal organ specialized for respiratory gas exchange with air.

luteinizing hormone (LH) A gonadotropin produced by the anterior pituitary that stimulates the gonads to produce sex hormones.

lymph [L. *lymph*a: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

lymph node A specialized structure in the vessels of the lymphatic system. Lymph nodes contain lymphocytes, which encounter and respond to foreign cells and molecules in the lymph as it passes through the vessels.

lymphatic system A system of vessels that returns interstitial fluid to the blood.

lymphocyte One of the two major classes of white blood cells; includes T cells, B cells, and other cell types important in the immune system.

lymphoid tissues Tissues of the immune system that are dispersed throughout the body, consisting of the thymus, spleen, bone marrow, and lymph nodes.

lysis (lie' sis) [Gk. *lysis*: break apart] Bursting of a cell.

lysogeny A form of viral replication in which the virus becomes incorporated into the host chromosome and remains inactive. Also called a lysogenic cycle. (Contrast with lytic cycle.)

lysosome (lie' so soam) [Gk. *lysis*: break away + *soma*: body] A membrane-enclosed organelle originating from the Golgi apparatus and containing hydrolytic enzymes. (Contrast with secondary lysosome.)

lysozyme (lie' so zyme) An enzyme in saliva, tears, and nasal secretions that hydrolyzes bacterial cell walls.

lytic cycle A viral reproductive cycle in which the virus takes over a host cell's synthetic machinery to replicate itself, then bursts (lyses) the host cell, releasing the new viruses. (Contrast with lysogeny.)

- M -

M phase The portion of the cell cycle in which mitosis takes place.

macroevolution [Gk. *makros*: large] Evolutionary changes occurring over long time spans and usually involving changes in many traits. (Contrast with microevolution.)

macromolecule A giant (molecular weight > 1,000) polymeric molecule. The macromolecules are the proteins, polysaccharides, and nucleic acids.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

macrophage (mac' roh faj) Phagocyte that engulfs pathogens by endocytosis.

MADS box DNA-binding domain in many plant transcription factors that is active in development.

maintenance methylase An enzyme that catalyzes the methylation of the new DNA strand when DNA is replicated.

major histocompatibility complex (MHC) A complex of linked genes, with multiple alleles, that control a number of cell surface antigens that identify self and can lead to graft rejection.

malignant Pertaining to a tumor that can grow indefinitely and/or spread from the original site of growth to other locations in the body. (Contrast with benign.)

Malpighian tubule (mal pee' gy un) A type of protonephridium found in insects.

map unit The distance between two genes as calculated from genetic crosses; a recombination frequency.

marine [L. *mare*: sea, ocean] Pertaining to or living in the ocean. (Contrast with aquatic, terrestrial.)

mark-recapture method A method of estimating population sizes of mobile organisms by capturing, marking, and releasing a sample of individuals, then capturing another sample at a later time.

mass extinction A period of evolutionary history during which rates of extinction are much higher than during intervening times.

mass number The sum of the number of protons and neutrons in an atom's nucleus.

mast cells Cells, typically found in connective tissue, that release histamine in response to tissue damage.

maternal effect genes Genes coding for morphogens that determine the polarity of the egg and larva in fruit flies.

mating type A particular strain of a species that is incapable of sexual reproduction with another member of the same strain but capable of sexual reproduction with members of other strains of the same species.

maximum likelihood A statistical method of determining which of two or more hypotheses

(such as phylogenetic trees) best fit the observed data, given an explicit model of how the data were generated.

mechanically gated channel A molecular channel that opens or closes in response to mechanical force applied to the plasma membrane in which it is inserted.

mechanoreceptor A cell that is sensitive to physical movement and generates action potentials in response.

medulla (meh dull' luh) (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brainstem that connects to the spinal cord.

medusa (plural: medusae) In cnidarians, a free-swimming, sexual life cycle stage shaped like a bell or an umbrella.

megaphyll The generally large leaf of a fern, horsetail, or seed plant, with several to many veins. (Contrast with microphyll.)

megaspore [Gk. *megas*: large + *spora*: to sow] In plants, a haploid spore that produces a female gametophyte.

megastrobilus In conifers, the female (seed-bearing) cone. (Contrast with microstrobilus.)

meiosis (my oh' sis) [Gk. *meiosis*: diminution] Division of a diploid nucleus to produce four haploid daughter cells. The process consists of two successive nuclear divisions with only one cycle of chromosome replication. In *meiosis I*, homologous chromosomes separate but retain their chromatids. The second division *meiosis II*, is similar to mitosis, in which chromatids separate.

melatonin A hormone released by the pineal gland. Involved in photoperiodicity and circadian rhythms.

membrane potential The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

membranous bone A type of bone that develops by forming on a scaffold of connective tissue. (Contrast with cartilage bone.)

memory cells Long-lived lymphocytes produced by exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

Mendel's laws See independent assortment; segregation.

meristem [Gk. *meristos*: divided] Plant tissue made up of undifferentiated actively dividing cells.

meristem identity genes In angiosperms, a group of genes whose expression initiates flower formation, probably by switching meristem cells from a vegetative to a reproductive fate.

mesenchyme (mez' en kyme) [Gk. *mesos*: middle + *enchyma*: infusion] Embryonic or unspecialized cells derived from the mesoderm.

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

mesoglea (mez' uh glee uh) [Gk. *mesos*: middle + *gloia*, glue] A thick, gelatinous noncellular layer that separates the two cellular tissue layers of ctenophores, cnidarians, and scyphozoans.

mesophyll (mez' uh fill) [Gk. *mesos*: middle + *phylon*: leaf] Chloroplast-containing, photosynthetic cells in the interior of leaves.

messenger RNA (mRNA) Transcript of a region of one of the strands of DNA; carries information (as a sequence of codons) for the synthesis of one or more proteins.

meta- [Gk.: between, along with, beyond] Prefix denoting a change or a shift to a new form or level; for example, as used in metamorphosis.

metabolic pathway A series of enzyme-catalyzed reactions so arranged that the product of one reaction is the substrate of the next.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

metabolome The quantitative description of all the small molecules in a cell or organism.

metabotropic receptor A receptor that indirectly alters membrane permeability to a type of ion when it combines with its ligand.

metagenomics The practice of analyzing DNA from environmental samples without isolating intact organisms.

metamorphosis (met' a mor' fo sis) [Gk. *meta*: between + *morphe*: form, shape] A change occurring between one developmental stage and another, as for example from a tadpole to a frog. (See complete metamorphosis, incomplete metamorphosis.)

metanephridia The paired excretory organs of annelids.

metaphase (met' a phase) The stage in nuclear division at which the centromeres of the highly supercoiled chromosomes are all lying on a plane (the metaphase plane or plate) perpendicular to a line connecting the division poles.

metapopulation A population divided into subpopulations, among which there are occasional exchanges of individuals.

metastasis (meh tass' tuh sis) The spread of cancer cells from their original site to other parts of the body.

methylation The addition of a methyl group ($-\text{CH}_3$) to a molecule.

MHC See major histocompatibility complex.

micelle A particle of lipid covered with bile salts that is produced in the duodenum and facilitates digestion and absorption of lipids.

microclimate A subset of climatic conditions in a small specific area, which generally differ from those in the environment at large, as in an animal's underground burrow.

microevolution Evolutionary changes below the species level, affecting allele frequencies. (Contrast with macroevolution.)

microfibril Crosslinked cellulose polymers, forming strong aggregates in the plant cell wall.

microfilament In eukaryotic cells, a fibrous structure made up of actin monomers. Microfilaments play roles in the cytoskeleton, in cell movement, and in muscle contraction.

microglia Glial cells that act as macrophages and mediators of inflammatory responses in the central nervous system.

micronutrient In plants, a mineral element required in concentrations of less than 100 micrograms per gram of plant dry matter; in animals, a mineral element required in concentrations of

less than 100 micrograms per day. (Contrast with macronutrient.)

microphyll A small leaf with a single vein, found in club mosses and their relatives. (Contrast with megaphyll.)

micropyle (mike' roh pile) [Gk. *mikros*: small + *pylon*: gate] Opening in the integument(s) of a seed plant ovule through which pollen grows to reach the female gametophyte within.

microRNA A small, noncoding RNA molecule, typically about 21 bases long, that binds to mRNA to inhibit its translation.

microspore [Gk. *mikros*: small + *spora*: to sow] In plants, a haploid spore that produces a male gametophyte.

microstrobilus In conifers, male pollen-bearing cone. (Contrast with megastrobilus.)

microtubules Tubular structures found in centrioles, spindle apparatus, cilia, flagella, and cytoskeleton of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

microvilli (sing.: microvillus) Projections of epithelial cells, such as the cells lining the small intestine, that increase their surface area.

midbrain One of the three regions of the vertebrate brain. Part of the brainstem, it serves as a relay station for sensory signals sent to the cerebral hemispheres.

middle lamella (la mell' ah) [L. *lamina*: thin sheet] A layer of polysaccharides that separates plant cells; a shared middle lamella lies outside the primary walls of the two cells.

mineral nutrients Inorganic ions required by organisms for normal growth and reproduction.

mismatch repair A mechanism that scans DNA after it has been replicated and corrects any base-pairing mismatches.

missense mutation A change in a gene's sequence that results in a change in the sequence of the amino acid specified by the corresponding codon. (Contrast with frame-shift mutation, nonsense mutation, silent mutation.)

mitochondrial matrix The fluid interior of the mitochondrion, enclosed by the inner mitochondrial membrane.

mitochondrion (my' toe kon' dree un) (plural: mitochondria) [Gk. *mitos*: thread + *chondros*: grain] An organelle in eukaryotic cells that contains the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

mitosis (my toe' sis) [Gk. *mitos*: thread] Nuclear division in eukaryotes leading to the formation of two daughter nuclei, each with a chromosome complement identical to that of the original nucleus.

model systems Also known as model organisms, these include the small group of species that are the subject of extensive research. They are organisms that adapt well to laboratory situations and findings from experiments on them can apply across a broad range of species. Classic examples include white rats and the fruit fly *Drosophila*.

moderately repetitive sequences DNA sequences repeated 10–1,000 times in the eukaryotic genome. They include the genes that code for rRNAs and tRNAs, as well as the DNA in telomeres.

Modern Synthesis An understanding of evolutionary biology that emerged in the early twentieth century as the principles of evolution were

integrated with the principles of modern genetics.

modularity In evolutionary developmental biology, the principle that the molecular pathways that determine different developmental processes operate independently from one another. See also developmental module.

mole A quantity of a compound whose weight in grams is numerically equal to its molecular weight expressed in atomic mass units. Avogadro's number of molecules: 6.023×10^{23} molecules.

molecular clock The approximately constant rate of divergence of macromolecules from one another over evolutionary time; used to date past events in evolutionary history.

molecular evolution The scientific study of the mechanisms and consequences of the evolution of macromolecules.

molecular tool kit A set of developmental genes and proteins that is common to most animals and is hypothesized to be responsible for the evolution of their differing developmental pathways.

molecular weight The sum of the atomic weights of the atoms in a molecule.

molecule A chemical substance made up of two or more atoms joined by covalent bonds or ionic attractions.

molting The process of shedding part or all of an outer covering, as the shedding of feathers by birds or of the entire exoskeleton by arthropods.

monoclonal antibody Antibody produced in the laboratory from a clone of hybridoma cells, each of which produces the same specific antibody.

monoculture In agriculture, a large-scale planting of a single species of domesticated crop plant.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

monohybrid cross A mating in which the parents differ with respect to the alleles of only one locus of interest.

monomer [Gk. *mono*: one + *meros*: unit] A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

monophyletic (mon' oh fih leht' ik) [Gk. *mono*: one + *phylon*: tribe] Pertaining to a group that consists of an ancestor and all of its descendants. (Contrast with paraphyletic, polyphyletic.)

monosaccharide A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

monosomic Pertaining to an organism with one less than the normal diploid number of chromosomes.

monosynaptic reflex A neural reflex that begins in a sensory neuron and makes a single synapse before activating a motor neuron.

morphogen A diffusible substance whose concentration gradient determines a developmental pattern in animals and plants.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

morphological species concept The definition of a species as a group of individuals that look alike. (Contrast with biological species concept; lineage species concept.)

morphology (more fol' o jee) [Gk. *morphe*: form + *logos*: study, discourse] The scientific study of organic form, including both its development and function.

mosaic development Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

motif See structural motif.

motile (mo' tul) Able to move from one place to another. (Contrast with sessile.)

motor cortex The region of the cerebral cortex that contains motor neurons that directly stimulate specific muscle fibers to contract.

motor neuron A neuron carrying information from the central nervous system to a cell that produces movement.

motor proteins Specialized proteins that use energy to change shape and move cells or structures within cells. See dynein, kinesin.

motor unit A motor neuron and the muscle fibers it controls.

mouth An opening through which food is taken in, located at the anterior end of a tubular gut.

mRNA See messenger RNA.

mucosal epithelium An epithelial cell layer containing cells that secrete mucus; found in the digestive and respiratory tracts. Also called mucosa.

Müllerian mimicry Convergence in appearance of two or more unpalatable species.

multipotent Having the ability to differentiate into a limited number of cell types. (Contrast with pluripotent, totipotent.)

muscle fiber A single muscle cell. In the case of skeletal muscle, a syncytial, multinucleate cell.

muscle tissue Excitable tissue that can contract through the interactions of actin and myosin; one of the four major tissue types in multicellular animals. There are three types of muscle tissue: skeletal, smooth, and cardiac.

mutagen (mute' ah jen) [L. *mutare*: change + Gk. *genesis*: source] Any agent (e.g., chemicals, radiation) that increases the mutation rate.

mutation A change in the genetic material not caused by recombination.

mutualism A type of interaction between species that benefits both species.

mycelium (my seel' ee yum) [Gk. *mykes*: fungus] In the fungi, a mass of hyphae.

mycorrhiza (my' ko rye' za) (plural: mycorrhizae) [Gk. *mykes*: fungus + *rhiza*: root] An association of the root of a plant with the mycelium of a fungus.

myelin (my' a lin) Concentric layers of plasma membrane that form a sheath around some axons; myelin provides the axon with electrical insulation and increases the rate of transmission of action potentials.

myocardial infarction Blockage of an artery that carries blood to the heart muscle.

myofibril (my' oh fy' bril) [Gk. *mys*: muscle + L. *fibrilla*: small fiber] A polymeric unit of actin and myosin in a muscle.

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

myosin One of the two contractile proteins of muscle.

- N -

natural killer cell A type of lymphocyte that attacks virus-infected cells and some tumor cells as well as antibody-labeled target cells.

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

nauplius (naw' plee us) [Gk. *nauplios*: shellfish] A bilaterally symmetrical larval form typical of crustaceans.

necrosis (nec roh' sis) [Gk. *nekros*: death] Premature cell death caused by external agents such as toxins.

negative feedback In regulatory systems, information that decreases a regulatory response, returning the system to the set point. (Contrast with positive feedback.)

negative regulation A type of gene regulation in which a gene is normally transcribed, and the binding of a repressor protein to the promoter prevents transcription. (Contrast with positive regulation.)

nematocyst (ne mat' o sist) [Gk. *nema*: thread + *kystis*: cell] An elaborate, threadlike structure produced by cells of jellyfishes and other cnidarians, used chiefly to paralyze and capture prey.

nephron (nef' ron) [Gk. *nephros*: kidney] The functional unit of the kidney, consisting of a structure for receiving a filtrate of blood and a tubule that reabsorbs selected parts of the filtrate.

Nernst equation A mathematical statement that calculates the potential across a membrane permeable to a single type of ion that differs in concentration on the two sides of the membrane.

nerve A structure consisting of many neuronal axons and connective tissue.

nervous tissue Tissue specialized for processing and communicating information; one of the four major tissue types in multicellular animals.

net primary productivity (NPP) The rate at which energy captured by photosynthesis is incorporated into the bodies of primary producers bodies through growth and reproduction.

net primary production The amount of primary producer biomass made available for consumption by heterotrophs.

neural network An organized group of neurons that contains three functional categories of neurons—afferent neurons, interneurons, and efferent neurons—and is capable of processing information.

neural tube An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior–posterior body axis.

neurohormone A chemical signal produced and released by neurons that subsequently acts as a hormone.

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

neuron (noor' on) [Gk. *neuron*: nerve] A nervous system cell that can generate and conduct action potentials along an axon to a synapse with another cell.

neurotransmitter A substance produced in and released by a neuron (the presynaptic cell) that diffuses across a synapse and excites or inhibits another cell (the postsynaptic cell).

neurulation Stage in vertebrate development during which the nervous system begins to form.

neutral allele An allele that does not alter the functioning of the proteins for which it codes.

neutral theory A view of molecular evolution that postulates that most mutations do not affect the amino acid being coded for, and that such mutations accumulate in a population at rates driven by genetic drift and mutation rates.

neutron (new' tron) One of the three fundamental particles of matter (along with protons and electrons), with mass approximately 1 amu and no electrical charge.

niche (nitch) [L. *nidus*: nest] The set of physical and biological conditions a species requires to survive, grow, and reproduce. (See also fundamental niche, realized niche.)

nitrate reduction The process by which nitrate (NO_3^-) is reduced to ammonia (NH_3).

nitric oxide (NO) An unstable molecule (a gas) that serves as a second messenger causing smooth muscle to relax. In the nervous system it operates as a neurotransmitter.

nitrifiers Chemolithotrophic bacteria that oxidize ammonia to nitrate in soil and in seawater.

nitrogen fixation Conversion of atmospheric nitrogen gas (N_2) into a more reactive and biologically useful form (ammonia), which makes nitrogen available to living things. Carried out by nitrogen-fixing bacteria, some of them free-living and others living within plant roots.

nitrogenase An enzyme complex found in nitrogen-fixing bacteria that mediates the stepwise reduction of atmospheric N_2 to ammonia and which is strongly inhibited by oxygen.

node [L. *nodus*: knob, knot] In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached.

node of Ranvier A gap in the myelin sheath covering an axon; the point where the axonal membrane can fire action potentials.

nodule A specialized structure in the roots of nitrogen-fixing plants that houses nitrogen-fixing bacteria, in which oxygen is maintained at a low level by leghemoglobin.

noncompetitive inhibitor A nonsubstrate that inhibits the activity of an enzyme by binding to a site other than its active site. (Contrast with competitive inhibitor.)

noncyclic electron transport In photosynthesis, the flow of electrons that forms ATP, NADPH, and O_2 .

nondisjunction Failure of sister chromatids to separate in meiosis II or mitosis, or failure of homologous chromosomes to separate in meiosis I. Results in aneuploidy.

nonpolar Having electric charges that are evenly balanced from one end to the other. (Contrast with polar.)

nonrandom mating Selection of mates on the basis of a particular trait or group of traits.

nonsense mutation Change in a gene's sequence that prematurely terminates translation by changing one of its codons to a stop codon.

nonsynonymous substitution A change in a gene from one nucleotide to another that changes the amino acid specified by the corresponding codon (i.e., AGC → AGA, or serine → arginine). (Contrast with synonymous substitution.)

norepinephrine A neurotransmitter found in the central nervous system and also at the post-ganglionic nerve endings of the sympathetic nervous system. Also called noradrenaline.

normal flora Microorganisms that normally live and reproduce on or in the body without causing disease, and which form a nonspecific defense against pathogens by competing with them for space and nutrients.

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

nucleic acid hybridization A technique in which a single-stranded nucleic acid probe is made that is complementary to, and binds to, a target sequence, either DNA or RNA. The resulting double-stranded molecule is a hybrid.

nucleoid (new' klee oid) The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

nucleolus (new klee' oh lus) A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

nucleoside A nucleotide without the phosphate group; a nitrogenous base attached to a sugar.

nucleosome A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

nucleotide substitution A change of one base pair to another in a DNA sequence.

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

nutrient A food substance; or, in the case of mineral nutrients, an inorganic element required for completion of the life cycle of an organism.

- O -

obligate anaerobe An anaerobic prokaryote that cannot survive exposure to O₂.

odorant A molecule that can bind to an olfactory receptor.

oil A triglyceride that is liquid at room temperature. (Contrast with fat.)

Okazaki fragments Newly formed DNA making up the lagging strand in DNA replication. DNA ligase links Okazaki fragments together to give a continuous strand.

olfactory [L. *olfacere*: to smell] Pertaining to the sense of smell (*olfaction*).

oligodendrocyte A type of glial cell that myelinates axons in the central nervous system.

oligosaccharide A polymer containing a small number of monosaccharides.

ommatidia [Gk. *omma*: eye] The units that make up the compound eye of some arthropods.

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that eats both animal and plant material. (Contrast with carnivore, detritivore, herbivore.)

oncogene [Gk. *onkos*: mass, tumor + *genes*: born] A gene that codes for a protein product that stimulates cell proliferation. Mutations in oncogenes that result in excessive cell proliferation can give rise to cancer.

oocyte See primary oocyte, secondary oocyte.

oogenesis (oh' eh jen e sis) [Gk. *oon*: egg + *genesis*: source] Gametogenesis leading to production of an ovum.

oogonium (oh' eh go' nee um) (plural: oogonia) (1) In some algae and fungi, a cell in which an egg is produced. (2) In animals, the diploid progeny of a germ cell in females.

operator The region of an operon that acts as the binding site for the repressor.

open circulatory system Circulatory system in which extracellular fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the circulatory system to be pumped out again. (Contrast with closed circulatory system.)

operon A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

opportunity cost The sum of the benefits an animal forfeits by not being able to perform some other behavior during the time when it is performing a given behavior.

opsin (op' sin) [Gk. *opsis*: sight] The protein portion of the visual pigment rhodopsin. (See rhodopsin.)

optic chiasm [Gk. *chiasma*: cross] Structure on the lower surface of the vertebrate brain where the two optic nerves come together.

optical isomers Two isomers that are mirror images of each other.

optimal foraging theory The application of a cost-benefit approach to feeding behavior to identify the fitness value of feeding choices.

orbital A region in space surrounding the atomic nucleus in which an electron is most likely to be found.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

organ identity genes In angiosperms, genes that specify the different organs of the flower. (Compare with homeotic genes.)

organ of Corti Structure in the inner ear that transforms mechanical forces produced from pressure waves ("sound waves") into action potentials that are sensed as sound.

organ system An interrelated and integrated group of tissues and organs that work together in a physiological function.

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

organic (1) Pertaining to any chemical compound that contains carbon. (2) Pertaining to any aspect of living matter, e.g., to its evolution, structure, or chemistry.

organism Any living entity.

organizer Region of the early amphibian embryo that directs early embryonic development. Also known as the primary embryonic organizer.

organogenesis The formation of organs and organ systems during development.

origin of replication (*ori*) DNA sequence at which helicase unwinds the DNA double helix and DNA polymerase binds to initiate DNA replication.

orthology (or thol' o jee) Type of homology in which the divergence of homologous genes can be traced to speciation events. (Contrast with paralogy.)

osmoconformer An aquatic animal that equilibrates the osmolarity of its extracellular fluid that is the same as with that of the external environment.

osmolarity The concentration of osmotically active particles in a solution.

osmoregulation Regulation of the chemical composition of the body fluids of an organism.

osmosis (oz mo' sis) [Gk. *osmos*: to push] Movement of water across a differentially permeable membrane, from one region to another region where the water potential is more negative.

ossicle (oss' ick ul) [L. *os*: bone] The calcified construction unit of echinoderm skeletons.

osteoblast (oss' tee oh blast) [Gk. *osteon*: bone + *blastos*: sprout] A cell that lay down the protein matrix of bone.

osteoclast (oss' tee oh clast) [Gk. *osteon*: bone + *klastos*: broken] A cell that dissolves bone.

osteocyte An osteoblast that has become enclosed in lacunae within the bone it has built.

outgroup In phylogenetics, a group of organisms used as a point of reference for comparison with the groups of primary interest (the in-group).

oval window The flexible membrane that, when moved by the bones of the middle ear, produces pressure waves in the inner ear.

ovarian cycle In human females, the monthly cycle of events by which eggs and hormones are produced. (Contrast with uterine cycle).

ovary (oh' var ee) [L. *ovum*: egg] Any female organ, in plants or animals, that produces an egg.

overtopping Plant growth pattern in which one branch differentiates from and grows beyond the others.

oviduct In mammals, the tube serving to transport eggs to the uterus or to outside of the body.

oviparity Reproduction in which eggs are released by the female and development is external to the mother's body. (Contrast with viviparity.)

ovoviviparity Pertaining to reproduction in which fertilized eggs develop and hatch within the mother's body but are not attached to the mother by means of a placenta.

ovulation Release of an egg from an ovary.

ovule (oh' vule) In plants, a structure comprising the megasporangium and the integument, which develops into a seed after fertilization.

ovum (oh' vum) (plural: ova) [L. egg] The female gamete.

oxidation (ox i day' shun) Relative loss of electrons in a chemical reaction; either outright removal to form an ion, or the sharing of electrons with substances having a greater affinity for them, such as oxygen. Most oxidations, including biological ones, are associated with the liberation of energy. (Contrast with reduction.)

oxidative phosphorylation ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

oxygenase An enzyme that catalyzes the addition of oxygen to a substrate from O₂.

oxytocin A hormone released by the posterior pituitary that promotes social bonding.

- P -

pancreas (pan' cree us) A gland located near the stomach of vertebrates that secretes digestive enzymes into the small intestine and releases insulin into the bloodstream.

Pangaea (pan jee' uh) [Gk. *pan*: all, every] The single land mass formed when all the continents came together in the Permian period.

para- [Gk. *para*: akin to, beside] Prefix indicating association in being along side or accessory to.

parabronchi Passages in the lungs of birds through which air flows.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

paralogy (par al' o jee) Type of homology in which the divergence of homologous genes can be traced to gene duplication events. (Contrast with orthology.)

paraphyletic (par' a fih leht' ik) [Gk. *para*: beside + *phylon*: tribe] Pertaining to a group that consists of an ancestor and some, but not all, of its descendants. (Contrast with monophyletic, polyphyletic.)

parasite An organism that consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

parasympathetic nervous system The division of the autonomic nervous system that works in opposition to the sympathetic nervous system. (Contrast with sympathetic nervous system.)

parathyroid glands Four glands on the posterior surface of the thyroid gland that produce and release parathyroid hormone.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that stimulates osteoclast activity and raises blood calcium levels. Also called parathormone.

parenchyma (pair eng' kyma) A plant tissue composed of relatively unspecialized cells without secondary walls.

parent rock The soil horizon consisting of the rock that is breaking down to form the soil. Also called bedrock, or the C horizon.

parental (P) generation The individuals that mate in a genetic cross. Their offspring are the first filial (F₁) generation.

parsimony Preferring the simplest among a set of plausible explanations of any phenomenon.

parthenocarp Formation of fruit from a flower without fertilization.

parthenogenesis [Gk. *parthenos*: virgin] Production of an organism from an unfertilized egg.

particulate theory In genetics, the theory that genes are physical entities that retain their identities after fertilization.

passive transport Diffusion across a membrane; may or may not require a channel or carrier protein. (Contrast with active transport.)

patch clamping A technique for isolating a tiny patch of membrane to allow the study of ion movement through a particular channel.

pathogen (path' o jen) [Gk. *pathos*: suffering + *genesis*: source] An organism that causes disease.

pattern formation In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

pedigree The pattern of transmission of a genetic trait within a family.

pelagic zone [Gk. *pelagos*: sea] The open ocean.

penetrance The proportion of individuals with a particular genotype that show the expected phenotype.

penis An accessory sex organ of male animals that enables the male to deposit sperm in the female's reproductive tract.

pentose [Gk. *penta*: five] A sugar containing five carbon atoms.

PEP carboxylase The enzyme that combines carbon dioxide with PEP to form a 4-carbon dicarboxylic acid at the start of C₄ photosynthesis or of crassulacean acid metabolism (CAM).

pepsin [Gk. *pepsis*: digestion] An enzyme in gastric juice that digests protein.

pepsinogen Inactive secretory product that is converted into pepsin by low pH or by enzymatic action.

peptide linkage The bond between amino acids in a protein; formed between a carboxyl group and amino group (CO—NH⁺) with the loss of water molecules.

peptidoglycan The cell wall material of many bacteria, consisting of a single enormous molecule that surrounds the entire cell.

perennial (per ren' ee al) [L. *per*: throughout + *annus*: year] A plant that survives from year to year. (Contrast with annual, biennial.)

perfect flower A flower with both stamens and carpels; a hermaphroditic flower. (Contrast with imperfect flower.)

pericycle [Gk. *peri*: around + *kyklos*: ring or circle] In plant roots, tissue just within the endodermis, but outside of the root vascular tissue. Meristematic activity of pericycle cells produces lateral root primordia.

periderm The outer tissue of the secondary plant body, consisting primarily of cork.

period (1) A category in the geological time scale. (2) The duration of a single cycle in a cyclical event, such as a circadian rhythm.

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

peristalsis (pair' i stall' sis) Wavelike muscular contractions proceeding along a tubular organ, propelling the contents along the tube.

peritoneum The mesodermal lining of the body cavity in coelomate animals.

peroxisome An organelle that houses reactions in which toxic peroxides are formed and then converted to water.

petal [Gk. *petalon*: spread out] In an angiosperm flower, a sterile modified leaf, nonphotosynthetic, frequently brightly colored, and often serving to attract pollinating insects.

petiole (pet' ee ole) [L. *petiolus*: small foot] The stalk of a leaf.

pH The negative logarithm of the hydrogen ion concentration; a measure of the acidity of a solution. A solution with pH = 7 is said to be neutral; pH values higher than 7 characterize basic solutions, while acidic solutions have pH values less than 7.

phage (fayj) See bacteriophage.

phagocyte [Gk. *phagein*: to eat + *kystos*: sac] One of two major classes of white blood cells; one of the nonspecific defenses of animals; ingests invading microorganisms by phagocytosis.

phagocytosis Endocytosis by a cell of another cell or large particle.

pharming The use of genetically modified animals to produce medically useful products in their milk.

pharynx [Gk. throat] The part of the gut between the mouth and the esophagus.

phenotype (fee' no type) [Gk. *phainein*: to show] The observable properties of an individual resulting from both genetic and environmental factors. (Contrast with genotype.)

phenotypic plasticity See developmental plasticity.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

phosphate group The functional group —OPO₃H₂.

phosphodiester linkage The connection in a nucleic acid strand, formed by linking two nucleotides.

phospholipid A lipid containing a phosphate group; an important constituent of cellular membranes. (See lipid.)

phospholipid bilayer The basic structural unit of biological membranes; a sheet of phospholipids two molecules thick in which the phospholipids are lined up with their hydrophobic "tails" packed tightly together and their hydrophilic, phosphate-containing "heads" facing outward. Also called lipid bilayer.

phosphorylation Addition of a phosphate group.

photoautotroph An organism that obtains energy from light and carbon from carbon dioxide. (Contrast with chemolithotroph, chemoheterotroph, photoheterotroph.)

photoheterotroph An organism that obtains energy from light but must obtain its carbon from organic compounds. (Contrast with chemolithotroph, chemoheterotroph, photoautotroph.)

photon (foe' ton) [Gk. *photos*: light] A quantum of visible radiation; a "packet" of light energy.

photoperiodicity Control of an organism's physiological or behavioral responses by the length of the day or night.

photoreceptor (1) In plants, a pigment that triggers a physiological response when it absorbs a photon. (2) In animals, a sensory receptor cell that senses and responds to light energy.

photorespiration Light-driven uptake of oxygen and release of carbon dioxide, the carbon being derived from the early reactions of photosynthesis.

photosynthesis (foe tow sin' the sis) [literally, "synthesis from light"] Metabolic processes, carried out by green plants, by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

photosystem [Gk. *phos*: light + *systema*: assembly] A light-harvesting complex in the chloroplast thylakoid composed of pigments and proteins.

photosystem I In photosynthesis, the reactions that absorb light at 700 nm, passing electrons to ferredoxin and thence to NADPH. Rich in chlorophyll *a*.

photosystem II In photosynthesis, the reactions that absorb light at 660 nm, passing electrons to the electron transport chain in the chloroplast. Rich in chlorophyll *b*.

phototropins A class of blue light receptors that mediate phototropism and other plant responses.

phototropism [Gk. *phos*: light + *tropē*: turning] A directed plant growth response to light.

phycobillin Photosynthetic pigment that absorbs red, yellow, orange, and green light and is found in cyanobacteria and some red algae.

phylogenetic tree A graphic representation of lines of descent among organisms or their genes.

phylogeny (fy loj' e nee) [Gk. *phylon*: tribe, race + *genesis*: source] The evolutionary history of a particular group of organisms or their genes.

physiology (fiz' ee ol' o jee) [Gk. *physis*: natural form] The scientific study of the functions of living organisms and the individual organs, tissues, and cells of which they are composed.

phytoalexins Substances toxic to pathogens, produced by plants in response to fungal or bacterial infection.

phytochrome (fy' tow krome) [Gk. *phyton*: plant + *chroma*: color] A plant pigment regulating a large number of developmental and other phenomena in plants.

phytomers In plants, the repeating modules that compose a shoot, each consisting of one or more leaves, attached to the stem at a node; an internode; and one or more axillary buds.

phytoplankton Photosynthetic plankton.

phytoremediation A form of bioremediation that uses plants to clean up environmental pollution.

pigment A substance that absorbs visible light.

pineal gland Gland located between the cerebral hemispheres that secretes melatonin.

pinocytosis Endocytosis by a cell of liquid containing dissolved substances.

pistil [L. *pistillum*: pestle] The structure of an angiosperm flower within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually differentiated into ovary, style, and stigma.

pih In plants, relatively unspecialized tissue found within a cylinder of vascular tissue.

pituitary gland A small gland attached to the base of the brain in vertebrates. Its hormones control the activities of other glands. Also known as the hypophysis.

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

plankton Free-floating small aquatic organisms. Photosynthetic members of the plankton are referred to as phytoplankton.

planula (plan' yew la) [L. *planum*: flat] A free-swimming, ciliated larval form typical of the cnidarians.

plaque (plack) [Fr.: a metal plate or coin] (1) A circular clearing in a layer (lawn) of bacteria growing on the surface of a nutrient agar gel. (2) An accumulation of prokaryotic organisms on tooth enamel. Acids produced by these microorganisms cause tooth decay. (3) A region of arterial wall invaded by fibroblasts and fatty deposits. (See atherosclerosis.)

plasma (plaz' muh) The liquid portion of blood, in which blood cells and other particulates are suspended.

plasma cell An antibody-secreting cell that develops from a B cell; the effector cell of the humoral immune system.

plasma membrane The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a plasma membrane.

plasmid A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element; found in many bacteria. May replicate independently of the chromosome.

plasmodesma (plural: plasmodesmata) [Gk. *plassein*: to mold + *desmos*: band] A cytoplasmic strand connecting two adjacent plant cells.

plasmogamy The fusion of the cytoplasm of two cells. (Contrast with karyogamy.)

plastid Any of the plant cell organelles that house biochemical pathways for photosynthesis.

plate tectonics [Gk. *tekton*: builder] The scientific study of the structure and movements of Earth's lithospheric plates, which are the cause of continental drift.

platelet A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

pleiotropy (plee' a tro pee) [Gk. *pleion*: more] The determination of more than one character by a single gene.

pleural membrane [Gk. *pleuras*: rib, side] The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

pluripotent [L. *pluri*: many + *potens*: powerful] Having the ability to form all of the cells in the body. (Contrast with multipotent, totipotent.)

podocytes Cells of Bowman's capsule of the nephron that cover the capillaries of the glomerulus, forming filtration slits.

point mutation A mutation that results from the gain, loss, or substitution of a single nucleotide.

polar Having separate and opposite electric charges at two ends, or poles. (Contrast with nonpolar.)

polar body A nonfunctional nucleus produced by meiosis during oogenesis.

polar nuclei In angiosperms, the two nuclei in the central cell of the megagametophyte; following fertilization they give rise to the endosperm.

polarity (1) In chemistry, the property of unequal electron sharing in a covalent bond that defines a polar molecule. (2) In development, the difference between one end of an organism or structure and the other.

pollen [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

poly- [Gk. *poly*: many] A prefix denoting multiple entities.

poly A tail A long sequence of adenine nucleotides (50–250) added after transcription to the 3' end of most eukaryotic mRNAs.

polyandry Mating system in which one female mates with multiple males.

polygyny Mating system in which one male mates with multiple females.

polymer [Gk. *poly*: many + *meros*: unit] A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer, oligomer.)

polymerase chain reaction (PCR) An enzymatic technique for the rapid production of millions of copies of a particular stretch of DNA where only a small amount of the parent molecule is available.

polymorphic (pol' lee mor' fik) [Gk. *poly*: many + *morphe*: form, shape] Coexistence in a population of two or more distinct traits.

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

polypeptide A large molecule made up of many amino acids joined by peptide linkages. Large polypeptides are called proteins.

polyphyletic (pol' lee fih leh' ik) [Gk. *poly*: many + *phylon*: tribe] Pertaining to a group that consists of multiple distantly related organisms, and does not include the common ancestor of the group. (Contrast with monophyletic, paraphyletic.)

polyploidy (pol' lee ploid ee) The possession of more than two entire sets of chromosomes.

polyribosome (polysome) A complex consisting of a threadlike molecule of messenger RNA and several (or many) ribosomes. The ribosomes move along the mRNA, synthesizing polypeptide chains as they proceed.

polysaccharide A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

pons [L. *pons*: bridge] Region of the brainstem anterior to the medulla.

population Any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another.

population bottleneck A period during which only a few individuals of a normally large population survive.

population density The number of individuals of a population per unit of area or volume.

population dynamics The patterns and processes of change in populations.

population genetics The study of genetic variation and its causes within populations.

portal blood vessels Blood vessels that begin and end in capillary beds.

positive cooperativity Occurs when a molecule can bind several ligands and each one that binds alters the conformation of the molecule so that it can bind the next ligand more easily. The binding of four molecules of O₂ by hemoglobin is an example of positive cooperativity.

positive feedback In regulatory systems, information that amplifies a regulatory response, increasing the deviation of the system from the set point. (Contrast with negative feedback.)

positive regulation A form of gene regulation in which a regulatory macromolecule is needed to turn on the transcription of a structural gene; in its absence, transcription will not occur. (Contrast with negative regulation.)

post- [L. *postere*: behind, following after] Prefix denoting something that comes after.

postabsorptive state State in which no food remains in the gut and thus no nutrients are being absorbed. (Contrast with absorptive state.)

posterior Toward or pertaining to the rear. (Contrast with anterior.)

postsynaptic cell The cell that receives information from a neuron at a synapse. (Contrast with presynaptic neuron.)

postzygotic reproductive barriers Barriers to the reproductive process that occur after the union of the nuclei of two gametes. (Contrast with prezygotic reproductive barriers.)

potential energy Energy not doing work, such as the energy stored in chemical bonds. (Contrast with kinetic energy.)

precapillary sphincter A cuff of smooth muscle that can shut off the blood flow to a capillary bed.

pre-mRNA (precursor mRNA) Initial gene transcript before it is modified to produce functional mRNA. Also known as the primary transcript.

predator An organism that kills and eats other organisms.

prereplication complex In eukaryotes, a complex of proteins that binds to DNA at the initiation of DNA replication.

pressure flow model An effective model for phloem transport in angiosperms. It holds that sieve element transport is driven by an osmotically driven pressure gradient between source and sink.

pressure potential The hydrostatic pressure of an enclosed solution in excess of the surrounding atmospheric pressure. (Contrast with solute potential, water potential.)

presynaptic neuron The neuron that transmits information to another cell at a synapse. (Contrast with postsynaptic cell.)

prey [L. *praeda*: booty] An organism consumed by a predator as an energy source.

prezygotic reproductive barriers Barriers to the reproductive process that occur before the union of the nuclei of two gametes. (Contrast with postzygotic reproductive barriers.)

primary active transport Active transport in which ATP is hydrolyzed, yielding the energy required to transport an ion or molecule against its

concentration gradient. (Contrast with secondary active transport.)

primary cell wall In plant cells, a structure that forms at the middle lamella after cytokinesis, made up of cellulose microfibrils, hemicelluloses, and pectins. (Contrast with secondary cell wall.)

primary consumer An organism (herbivore) that eats plant tissues.

primary growth In plants, growth that is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. (Contrast with secondary growth.)

primary immune response The first response of the immune system to an antigen, involving recognition by lymphocytes and the production of effector cells and memory cells. (Contrast with secondary immune response.)

primary lysosome See lysosome.

primary meristem Meristem that produces the tissues of the primary plant body.

primary oocyte (oh' eh site) [Gk. *oon*: egg + *kytos*: container] The diploid progeny of an oogonium. In many species, a primary oocyte enters prophase of the first meiotic division, then remains in developmental arrest for a long time before resuming meiosis to form a secondary oocyte and a polar body.

primary plant body That part of a plant produced by primary growth. Consists of all the *nonwoody* parts of a plant; many herbaceous plants consist entirely of a primary plant body. (Contrast with secondary plant body.)

primary producer A photosynthetic or chemosynthetic organism that synthesizes complex organic molecules from simple inorganic ones.

primary sex determination Genetic determination of gametic sex, male or female. (Contrast with secondary sex determination.)

primary spermatocyte The diploid progeny of a spermatogonium; undergoes the first meiotic division to form secondary spermatocytes.

primary succession Succession that begins in an area initially devoid of life, such as on recently exposed glacial till or lava flows. (Contrast with secondary succession.)

primary structure The specific sequence of amino acids in a protein.

primase An enzyme that catalyzes the synthesis of a primer for DNA replication.

primer Strand of nucleic acid, usually RNA, that is the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

primordium (plural: primordia) [L. *origin*] The most rudimentary stage of an organ or other part.

prion An infectious protein that can proliferate by converting the inactive form of a particular protein into an active protein.

pro- [L.: first, before, favoring] A prefix often used in biology to denote a developmental stage that comes first or an evolutionary form that appeared earlier than another. For example, prokaryote, prophase.

probe A segment of single stranded nucleic acid used to identify DNA molecules containing the complementary sequence.

procambium Primary meristem that produces the vascular tissue.

procedural memory Memory of motor tasks. Cannot be consciously recalled and described. (Contrast with declarative memory.)

processive Pertaining to an enzyme that catalyzes many reactions each time it binds to a substrate, as DNA polymerase does during DNA replication.

progesterone [L. *pro*: favoring + *gestare*: to bear] A female sex hormone that maintains pregnancy.

prolactin A hormone released by the anterior pituitary, one of whose functions is the stimulation of milk production in female mammals.

proliferating cell nuclear antigen (PCNA) A protein complex that ensures processivity of DNA replication in eukaryotes.

prometaphase The phase of nuclear division that begins with the disintegration of the nuclear envelope.

promoter A DNA sequence to which RNA polymerase binds to initiate transcription.

prophage (pro' fayj) The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

prophase (pro' phase) The first stage of nuclear division, during which chromosomes condense from diffuse, threadlike material to discrete, compact bodies.

prostaglandin Any one of a group of specialized lipids with hormone-like functions. It is not clear that they act at any considerable distance from the site of their production.

prostate gland In male humans, surrounds the urethra at its junction with the vas deferens; supplies an acid-neutralizing fluid to the semen.

prosthetic group Any nonprotein portion of an enzyme.

proteasome In the eukaryotic cytoplasm, a huge protein structure that binds to and digests cellular proteins that have been tagged by ubiquitin.

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins.

protein kinase (kye' nase) An enzyme that catalyzes the addition of a phosphate group from ATP to a target protein.

protein kinase cascade A series of reactions in response to a molecular signal, in which a series of protein kinases activates one another in sequence, amplifying the signal at each step.

proteoglycan A glycoprotein containing a protein core with attached long, linear carbohydrate chains.

proteolysis [protein + Gk. *lysis*: break apart] An enzymatic digestion of a protein or polypeptide.

proteome The set of proteins that can be made by an organism. Because of alternative splicing of pre-mRNA, the number of proteins that can be made is usually much larger than the number of protein-coding genes present in the organism's genome.

protoderm Primary meristem that gives rise to the plant epidermis.

proton (pro' ton) [Gk. *protos*: first, before] (1) A subatomic particle with a single positive charge.

The number of protons in the nucleus of an atom determine its element. (2) A hydrogen ion, H^+ .

proton pump An active transport system that uses ATP energy to move hydrogen ions across a membrane, generating an electric potential.

proton-motive force Force generated across a membrane having two components: a chemical potential (difference in proton concentration) plus an electrical potential due to the electrostatic charge on the proton.

protonephridium The excretory organ of flatworms, made up of a tubule and a flame cell.

protoplast The living contents of a plant cell; the plasma membrane and everything contained within it.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

proximal Near the point of attachment or other reference point. (Contrast with distal.)

proximal convoluted tubule The initial segment of a renal tubule, closest to the glomerulus. (Compare with distal convoluted tubule.)

proximate cause The immediate genetic, physiological, neurological, and developmental mechanisms responsible for a behavior or morphology. (Contrast with ultimate cause.)

pseudocoelomate (soo' do see' low mate) [Gk. *pseudes*: false + *koiloma*: cavity] Having a body cavity, called a pseudocoel, consisting of a fluid-filled space in which many of the internal organs are suspended, but which is enclosed by mesoderm only on its outside.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

pseudopod (soo' do pod) [Gk. *pseudes*: false + *podos*: foot] A temporary, soft extension of the cell body that is used in location, attachment to surfaces, or engulfing particles.

pulmonary [L. *pulmo*: lung] Pertaining to the lungs.

pulmonary circuit The portion of the circulatory system by which blood is pumped from the heart to the lungs or gills for oxygenation and back to the heart for distribution. (Contrast with systemic circuit.)

pulmonary valve A one-way valve between the right ventricle of the heart and the pulmonary artery that prevents backflow of blood into the ventricle when it relaxes.

Punnett square Method of predicting the results of a genetic cross by arranging the gametes of each parent at the edges of a square.

pupa (pew' pa) [L. *pupa*: doll, puppet] In certain insects (the Holometabola), the encased developmental stage between the larva and the adult.

pupil The opening in the vertebrate eye through which light passes.

purine (pure' een) One of the two types of nitrogenous bases in nucleic acids. Each of the purines—adenine and guanine—pairs with a specific pyrimidine.

Purkinje fibers Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

pyrimidine (per im' a deen) One of the two types of nitrogenous bases in nucleic acids. Each

of the pyrimidines—cytosine, thymine, and uracil—pairs with a specific purine.

pyrogen Molecule that produces a rise in body temperature (fever); may be produced by an invading pathogen or by cells of the immune system in response to infection.

pyruvate A three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

pyruvate oxidation Conversion of pyruvate to acetyl CoA and CO_2 that occurs in the mitochondrial matrix in the presence of O_2 .

- Q -

Q_{10} A value that compares the rate of a biochemical process or reaction over $10^\circ C$ temperature ranges. A process that is not temperature-sensitive has a Q_{10} of 1; values of 2 or 3 mean the reaction speeds up as temperature increases.

quantitative trait loci A set of genes that determines a complex character that exhibits quantitative variation.

quaternary structure The specific three-dimensional arrangement of protein subunits.

- R -

R group The distinguishing group of atoms of a particular amino acid; also known as a side chain.

r-strategist A species whose life history strategy allows for a high intrinsic rate of population increase (r). (Contrast with K -strategist.)

radial symmetry The condition in which any two halves of a body are mirror images of each other, providing the cut passes through the center; a cylinder cut lengthwise down its center displays this form of symmetry.

radiation The transfer of heat from warmer objects to cooler ones via the exchange of infrared radiation. *See also* electromagnetic radiation; evolutionary radiation.

radicle An embryonic root.

radioisotope A radioactive isotope of an element. Examples are carbon-14 (^{14}C) and hydrogen-3, or tritium (3H).

reactant A chemical substance that enters into a chemical reaction with another substance.

reaction center A group of electron transfer proteins that receive energy from light-absorbing pigments and convert it to chemical energy by redox reactions.

realized niche A species' niche as defined by its interactions with other species. (Contrast with fundamental niche.)

receptive field The area of visual space that activates a particular cell in the visual system.

receptor *See* receptor protein, sensory receptor cell.

receptor-mediated endocytosis Endocytosis initiated by macromolecular binding to a specific membrane receptor.

receptor potential The change in the resting potential of a sensory cell when it is stimulated.

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

recessive In genetics, an allele that does not determine phenotype in the presence of a dominant allele. (Contrast with dominance.)

reciprocal adaptation *See* coevolution.

reciprocal crosses A pair of matings in one of which a female of genotype A mates with a male of genotype B and in the other of which a female of genotype B mates with a male of genotype A.

recognition sequence *See* restriction site.

recombinant Pertaining to an individual, meiotic product, or chromosome in which genetic materials originally present in two individuals end up in the same haploid complement of genes.

recombinant DNA A DNA molecule made in the laboratory that is derived from two or more genetic sources.

recombinant frequency The proportion of offspring of a genetic cross that have phenotypes different from the parental phenotypes due to crossing over between linked genes during gamete formation.

reconciliation ecology The practice of making exploited lands more biodiversity-friendly.

rectum The terminal portion of the gut, ending at the anus.

redox reaction A chemical reaction in which one reactant becomes oxidized and the other becomes reduced.

reduction Gain of electrons by a chemical reactant; any reduction is accompanied by an oxidation. (Contrast with oxidation.)

refractory period The time interval after an action potential during which another action potential cannot be elicited from an excitable membrane.

regeneration The development of a complete individual from a fragment of an organism.

regulative development A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

regulatory sequence A DNA sequence to which the protein product of a regulatory gene binds.

regulatory gene A gene that codes for a protein (or RNA) that in turn controls the expression of another gene.

regulatory system A system that uses feedback information to maintain a physiological function or parameter at an optimal level. (Contrast with controlled system.)

regulatory T cells (T_{reg}) Class of T cells that mediates tolerance to self antigens.

reinforcement The evolution of enhanced reproductive isolation between populations due to natural selection for greater isolation.

releaser Sensory stimulus that triggers performance of a stereotyped behavior pattern.

REM (rapid-eye-movement) sleep A sleep state characterized by vivid dreams, skeletal muscle relaxation, and rapid eye movements. (Contrast with slow-wave sleep.)

renal [L. *renes*: kidneys] Relating to the kidneys.

renal tubule A structural unit of the kidney that collects filtrate from the blood, reabsorbs specific ions, nutrients, and water and returns them to the blood, and concentrates excess ions and waste products such as urea for excretion from the body.

replication The duplication of genetic material.

replication complex The close association of several proteins operating in the replication of DNA.

replication fork A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

replicon A region of DNA replicated from a single origin of replication.

reporter gene A genetic marker included in recombinant DNA to indicate the presence of the recombinant DNA in a host cell.

repressor A protein encoded by a regulatory gene that can bind to a specific operator and prevent transcription of the operon. (Contrast with activator.)

reproductive isolation Condition in which two divergent populations are no longer exchanging genes. Can lead to speciation.

rescue effect The process by which individuals moving between subpopulations of a metapopulation may prevent declining subpopulations from becoming extinct.

resistance (R) genes Plant genes that confer resistance to specific strains of pathogens.

resource Something in the environment required by an organism for its maintenance and growth that is consumed in the process of being used.

resource partitioning A situation in which selection pressures resulting from interspecific competition cause changes in the ways in which the competing species use the limiting resource, thereby allowing them to coexist.

respiration (res pi ra' shun) [L. *spirare*: to breathe] (1) Cellular respiration. (2) Breathing.

respiratory chain The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

respiratory gases Oxygen (O₂) and carbon dioxide (CO₂); the gases that an animal must exchange between its internal body fluids and the outside medium (air or water).

resting potential The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential, electrotonic potential.)

restoration ecology The science and practice of restoring damaged or degraded ecosystems.

restriction enzyme Any of a type of enzyme that cleaves double-stranded DNA at specific sites; extensively used in recombinant DNA technology. Also called a restriction endonuclease.

restriction fragment length polymorphism See RFLP.

restriction point (R) The specific time during G1 of the cell cycle at which the cell becomes committed to undergo the rest of the cell cycle.

restriction site A specific DNA base sequence that is recognized and acted on by a restriction endonuclease.

reticular system A central region of the vertebrate brainstem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

retina (rett' in uh) [L. *rete*: net] The light-sensitive layer of cells in the vertebrate or cephalopod eye.

retinoblastoma protein A protein that inhibits an animal cell from passing through the restriction point; inactivation of this protein is necessary for the cell cycle to proceed.

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse genetics Method of genetic analysis in which a phenotype is first related to a DNA variation, then the protein involved is identified.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

RFLP Restriction fragment length polymorphism, the coexistence of two or more patterns of restriction fragments resulting from underlying differences in DNA sequence.

rhizoids (rye' zoids) [Gk. root] Hairlike extensions of cells in mosses, liverworts, and a few vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

rhizome (rye' zome) An underground stem (as opposed to a root) that runs horizontally beneath the ground.

rhodopsin A photopigment used in the visual process of transducing photons of light into changes in the membrane potential of photoreceptor cells.

ribonucleic acid See RNA.

ribose A five-carbon sugar in nucleotides and RNA.

ribosomal RNA (rRNA) Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

ribosome A small particle in the cell that is the site of protein synthesis.

ribozyme An RNA molecule with catalytic activity.

risk cost The increased chance of being injured or killed as a result of performing a behavior, compared to resting.

RNA (ribonucleic acid) An often single stranded nucleic acid whose nucleotides use ribose rather than deoxyribose and in which the base uracil replaces thymine found in DNA. Serves as genome from some viruses. (See rRNA, tRNA, mRNA, and ribozyme.)

RNA interference (RNAi) A mechanism for reducing mRNA translation whereby a double-stranded RNA, made by the cell or synthetically, is processed into a small, single-stranded RNA, whose binding to a target mRNA results in the latter's breakdown.

RNA polymerase An enzyme that catalyzes the formation of RNA from a DNA template.

RNA splicing The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

rod cells Light-sensitive cell in the vertebrate retina; these sensory receptor cells are sensitive in extremely dim light and are responsible for dim light, black and white vision.

root The organ responsible for anchoring the plant in the soil, absorbing water and minerals, and producing certain hormones. Some roots are storage organs.

root cap A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem; the organ that perceives the gravitational stimulus in root gravitropism.

root hair A long, thin process from a root epidermal cell that absorbs water and minerals from the soil solution.

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

rough endoplasmic reticulum (RER) The portion of the endoplasmic reticulum whose outer surface has attached ribosomes. (Contrast with smooth endoplasmic reticulum.)

rRNA See ribosomal RNA.

rubisco Contraction of ribulose biphosphate carboxylase/oxygenase, the enzyme that combines carbon dioxide or oxygen with ribulose biphosphate to catalyze the first step of photosynthetic carbon fixation or photorespiration, respectively.

ruminant Herbivorous, cud-chewing mammals such as cows or sheep, characterized by a stomach that consists of four compartments: the rumen, reticulum, omasum, and abomasum.

- S -

S phase In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G₁ phase, G₂ phase, M phase.)

saltatory conduction [L. *saltare*: to jump] The rapid conduction of action potentials in myelinated axons; so called because action potentials appear to "jump" between nodes of Ranvier along the axon.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter.

sarcomere (sark' o meer) [Gk. *sark*: flesh + *meros*: unit] The contractile unit of a skeletal muscle.

sarcoplasm The cytoplasm of a muscle cell.

sarcoplasmic reticulum The endoplasmic reticulum of a muscle cell.

saturated fatty acid A fatty acid in which all the bonds between carbon atoms in the hydrocarbon chain are single bonds—that is, all the bonds are saturated with hydrogen atoms. (Contrast with unsaturated fatty acid.)

scientific method A means of gaining knowledge about the natural world by making observations, posing hypotheses, and conducting experiments to test those hypotheses.

Schwann cell A type of glial cell that myelinates axons in the peripheral nervous system.

scion In horticulture, the bud or stem from one plant that is grafted to a root or root-bearing stem of another plant (the stock).

sclerenchyma (skler eng' kyma) [Gk. *skleros*: hard + *kymus*: juice] A plant tissue composed of cells with heavily thickened cell walls. The cells are dead at functional maturity. The principal types of sclerenchyma cells are fibers and sclereids.

second law of thermodynamics The principle that when energy is converted from one form to another, some of that energy becomes unavailable for doing work.

second messenger A compound, such as cAMP, that is released within a target cell after a hormone (the first messenger) has bound to a surface receptor on a cell; the second messenger triggers further reactions within the cell.

secondary active transport A form of active transport that does not use ATP as an energy source; rather, transport is coupled to ion diffu-

sion down a concentration gradient established by primary active transport.

secondary cell wall A thick, cellulosic structure internal to the primary cell wall formed in some plant cells after cell expansion stops (Contrast with primary cell wall.)

secondary consumer An organism that eat primary consumers.

secondary growth In plants, growth that contributes to an increase in girth. (Contrast with primary growth.)

secondary immune response A rapid and intense response to a second or subsequent exposure to an antigen, initiated by memory cells. (Contrast with primary immune response.)

secondary lysosome Membrane-enclosed organelle formed by the fusion of a primary lysosome with a phagosome, in which macromolecules taken up by phagocytosis are hydrolyzed into their monomers. (Contrast with lysosome.)

secondary metabolite A compound synthesized by a plant that is not needed for basic cellular metabolism. Typically has an antiherbivore or antiparasite function.

secondary plant body That part of a plant produced by secondary growth; consists of woody tissues. (Contrast with primary plant body.)

secondary sex determination Formation of secondary sexual characteristics (i.e., those other than gonads), such as external sex organs and body hair. (Contrast with primary sex determination.)

secondary spermatocyte One of the products of the first meiotic division of a primary spermatocyte.

secondary structure Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet.

secondary succession Succession after a disturbance that did not eliminate all the organisms originally living on the site. (Contrast with primary succession.)

secretin (si kree't in) A peptide hormone secreted by the upper region of the small intestine when acidic chyme is present. Stimulates the pancreatic duct to secrete bicarbonate ions.

sedimentary rock Rock formed by the accumulation of sediment grains on the bottom of a body of water.

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

segmentation Division of an animal body into segments.

segmentation genes Genes that determine the number and polarity of body segments.

segregation In genetics, the separation of alleles, or of homologous chromosomes, from each other during meiosis so that each of the haploid daughter nuclei produced contains one or the other member of the pair found in the diploid parent cell, but never both. This principle was articulated by Mendel as his first law.

selective permeability Allowing certain substances to pass through while other substances are excluded; a characteristic of membranes.

self-incompatibility In plants, the possession of mechanisms that prevent self-fertilization.

semelparous [L. *semel*: once + *pario*: to beget] Reproducing only once in a lifetime. (Contrast with iteroparous.)

semen (see' men) [L. *semin*: seed] The thick, whitish liquid produced by the male reproductive system in mammals, containing the sperm.

semiconservative replication The way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

seminiferous tubules The tubules within the testes within which sperm production occurs.

senescence [L. *senescere*: to grow old] Aging; deteriorative changes with aging; the increased probability of dying with increasing age.

sensitive period The life stage during which some particular type of learning must take place, or during which it occurs much more easily than at other times. Typical of song learning among birds.

sensor See sensory receptor cell.

sensory neuron A specialized neuron that transduces a particular type of sensory stimulus into action potentials.

sensory receptor cell Cell that is responsive to a particular type of physical or chemical stimulation.

sensory transduction The transformation of environmental stimuli or information into neural signals.

sepal (see' pul) [L. *sepalum*: covering] One of the outermost structures of the flower, usually protective in function and enclosing the rest of the flower in the bud stage.

septum (plural: septa) [L. wall] (1) A partition or cross-wall appearing in the hyphae of some fungi. (2) The bony structure dividing the nasal passages.

sequence alignment A method of identifying homologous positions in DNA or amino acid sequences by pinpointing the locations of deletions and insertions that have occurred since two (or more) organisms diverged from a common ancestor.

Sertoli cells Cells in the seminiferous tubules that nurture the developing sperm.

sessile (sess' ul) [L. *sedere*: to sit] Permanently attached; not able to move from one place to another. (Contrast with motile.)

set point In a regulatory system, the threshold sensitivity to the feedback stimulus.

sex chromosome In organisms with a chromosomal mechanism of sex determination, one of the chromosomes involved in sex determination.

sex linkage The pattern of inheritance characteristic of genes located on the sex chromosomes of organisms having a chromosomal mechanism for sex determination.

sexual reproduction Reproduction involving the union of gametes.

sexual selection Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in one sex as a result of competition among individuals of that sex for mates.

Shannon diversity index A formula for quantifying diversity that takes both species richness and species evenness into account; based on a mathematical expression of the certainty with which the next item sampled in a series can be predicted.

shared derived trait See synapomorphy.

shoot system In plants, the organ system consisting of the leaves, stem(s), and flowers.

short tandem repeat (STR) A short (1–5 base pairs), moderately repetitive sequence of DNA. The number of copies of an STR at a particular location varies between individuals and is inherited.

shotgun sequencing A relatively rapid method of DNA sequencing in which a DNA molecule is broken up into overlapping fragments, each fragment is sequenced, and high-speed computers analyze and realign the fragments. (Contrast with hierarchical sequencing.)

side chain See R group.

sieve tube element The characteristic cell of the phloem in angiosperms, which contains cytoplasm but relatively few organelles, and whose end walls (*sieve plates*) contain pores that form connections with neighboring cells.

signal sequence The sequence of a protein that directs the protein protein to a particular organelle.

signal transduction pathway The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

silent mutation A change in a gene's sequence that has no effect on the amino acid sequence of a protein because it occurs in noncoding DNA or because it does not change the amino acid specified by the corresponding codon. (Contrast with frame-shift mutation, missense mutation, nonsense mutation.)

similarity matrix A matrix used to compare the degree of divergence among pairs of objects. For molecular sequences, constructed by summing the number or percentage of nucleotides or amino acids that are identical in each pair of sequences.

single nucleotide polymorphisms (SNPs) Inherited variations in a single nucleotide base in DNA that differ between individuals.

single-strand binding protein In DNA replication, a protein that binds to single strands of DNA after they have been separated from each other, keeping the two strands separate for replication.

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

sinoatrial node (sigh' no ay' tree al) [L. *sinus*: curve + *atrium*: chamber] The pacemaker of the mammalian heart.

siRNAs (small interfering RNAs) Short, double-stranded RNA molecules used in RNA interference.

sister chromatid Each of a pair of newly replicated chromatids.

sister groups Two phylogenetic groups that are each other's closest relatives.

skeletal muscle A type of muscle tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also called striated muscle. (Contrast with cardiac muscle, smooth muscle.)

skeletal systems Organ systems that provide rigid supports against which muscles can pull to create directed movements.

sliding DNA clamp Protein complex that keeps DNA polymerase bound to DNA during replication.

sliding filament theory Mechanism of muscle contraction based on the formation and breaking of crossbridges between actin and myosin filaments, causing the filaments to slide together.

slow-wave sleep A state of deep, restorative sleep characterized by high-amplitude slow waves in the EEG. (Contrast with REM sleep.)

small intestine The portion of the gut between the stomach and the colon; consists of the duodenum, the jejunum, and the ileum.

small nuclear ribonucleoprotein particle (snRNP) A complex of an enzyme and a small nuclear RNA molecule, functioning in RNA splicing.

smooth endoplasmic reticulum (SER) Portion of the endoplasmic reticulum that lacks ribosomes and has a tubular appearance. (Contrast with rough endoplasmic reticulum.)

smooth muscle Muscle tissue consisting of sheets of mononucleated cells innervated by the autonomic nervous system. (Contrast with cardiac muscle, skeletal muscle.)

sodium–potassium (Na⁺–K⁺) pump Antiporter responsible for primary active transport; it pumps sodium ions out of the cell and potassium ions into the cell, both against their concentration gradients. Also called a sodium–potassium ATPase.

soil horizon See horizon.

solute A substance that is dissolved in a liquid (solvent) to form a solution.

solute potential A property of any solution, resulting from its solute contents; it may be zero or have a negative value. The more negative the solute potential, the greater the tendency of the solution to take up water through a differentially permeable membrane. (Contrast with pressure potential, water potential.)

solution A liquid (the solvent) and its dissolved solutes.

solvent Liquid in which a substance (solute) is dissolved to form a solution.

somatic cell [Gk. *soma*: body] All the cells of the body that are not specialized for reproduction. (Contrast with germ cell.)

somatic mutation Permanent genetic change in a somatic cell. These mutations affect the individual only; they are not passed on to offspring. (Contrast with germ line mutation.)

somatosensory cortex The region of the cerebral cortex that receives input from mechanosensors distributed throughout the body.

somatostatin Peptide hormone made in the hypothalamus that inhibits the release of other hormones from the pituitary and intestine.

somite (so' might) One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

Sorenson's index Mathematical formula that measures beta diversity.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

spatial summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations and hyperpolarizations produced at different sites on the postsynaptic cell. (Contrast with temporal summation.)

spawning See external fertilization.

speciation (spee' see ay' shun) The process of splitting one population into two populations that are reproductively isolated from one another.

species (spee' sees) [L. kind] The base unit of taxonomic classification, consisting of an ancestor–descendant group of populations of evolutionarily closely related, similar organisms. The more narrowly defined “biological species” consists of individuals capable of interbreeding with each other but not with members of other species.

species–area relationship The relationship between the size of an area and the numbers of species it supports.

species richness The total number of species living in a region.

specific defenses Defensive reactions of the vertebrate immune system that are based on the reaction of an antibody to a specific antigen. (Contrast with nonspecific defenses.)

specific heat The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

sperm [Gk. *sperma*: seed] The male gamete.

spermatid One of the products of the second meiotic division of a primary spermatocyte; four haploid spermatids, which remain connected by cytoplasmic bridges, are produced for each primary spermatocyte that enters meiosis.

spermatogenesis (spur mat' oh jen' e sis) [Gk. *sperma*: seed + *genesis*: source] Gametogenesis leading to the production of sperm.

spermatogonia In animals, the diploid progeny of a germ cell in males.

spherical symmetry The simplest form of symmetry, in which body parts radiate out from a central point such that an infinite number of planes passing through that central point can divide the organism into similar halves.

spicule [L. arrowhead] A hard, calcareous skeletal element typical of sponges.

spinal reflex The conversion of afferent to efferent information in the spinal cord without participation of the brain.

sphincter (sfin'k ter) [Gk. *sphinkter*: something that binds tightly] A ring of muscle that can close an orifice, for example, at the anus.

spindle Array of microtubules emanating from both poles of a dividing cell during mitosis and playing a role in the movement of chromosomes at nuclear division. Named for its shape.

spleen Organ that serves as a reservoir for venous blood and eliminates old, damaged red blood cells from the circulation.

spliceosome RNA–protein complex that splices out introns from eukaryotic pre-mRNAs.

splicing See RNA splicing.

spontaneous mutation A genetic change caused by internal cellular mechanisms, such as an error in DNA replication. (Contrast with induced mutation.)

sporangiophore A stalked reproductive structure produced by zygosporic fungi that extends from a hypha and bears one or many sporangia.

sporangium (spor an' gee um) (plural: sporangia) [Gk. *spora*: seed + *angeion*: vessel or reservoir] In plants and fungi, any specialized structure within which one or more spores are formed.

spore [Gk. *spora*: seed] (1) Any asexual reproductive cell capable of developing into an adult organism without gametic fusion. In plants, haploid spores develop into gametophytes, diploid spores into sporophytes. (2) In prokaryotes, a resistant cell capable of surviving unfavorable periods.

sporocyte Specialized cells of the diploid sporophyte that will divide by meiosis to produce four haploid spores. Germination of these spores produces the haploid gametophyte.

sporophyte (spor' o fyte) [Gk. *spora*: seed + *phyton*: plant] In plants and protists with alternation of generations, the diploid phase that produces the spores. (Contrast with gametophyte.)

stabilizing selection Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with disruptive selection.)

stamen (stay' men) [L. *stamen*: thread] A male (pollen-producing) unit of a flower, usually composed of an anther, which bears the pollen, and a filament, which is a stalk supporting the anther.

starch [O.E. *stearc*: stiff] A polymer of glucose; used by plants to store energy.

Starling's forces The two opposing forces responsible for water movement across capillary walls: blood pressure, which squeezes water and small solutes out of the capillaries, and osmotic pressure, which pulls water back into the capillaries.

start codon The mRNA triplet (AUG) that acts as a signal for the beginning of translation at the ribosome. (Contrast with stop codon.)

stele (steel) [Gk. *stylos*: pillar] The central cylinder of vascular tissue in a plant stem.

stem In plants, the organ that holds leaves and/or flowers and transports and distributes materials among the other organs of the plant.

stem cell In animals, an undifferentiated cell that is capable of continuous proliferation. A stem cell generates more stem cells and a large clone of differentiated progeny cells. (See also embryonic stem cell.)

steroid Any of a family of lipids whose multiple rings share carbons. The steroid cholesterol is an important constituent of membranes; other steroids function as hormones.

sticky ends On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends facilitate the joining of segments of DNA from different sources.

stigma [L. *stigma*: mark, brand] The part of the pistil at the apex of the style that is receptive to pollen, and on which pollen germinates.

stimulus [L. *stimulare*: to goad] Something causing a response; something in the environment detected by a receptor.

stock In horticulture, the root or root-bearing stem to which a bud or piece of stem from another plant (the scion) is grafted.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

stomatal crypt In plants, a sunken cavity below the leaf surface in which a stoma is sheltered from the drying effects of air currents.

stop codon Any of the three mRNA codons that signal the end of protein translation at the ribosome: UAG, UGA, UAA.

stratosphere The upper part of Earth's atmosphere, above the troposphere; extends from approximately 18 kilometers upward to approximately 50 kilometers above the surface.

stratum (plural *strata*) [L. *stratos*: layer] A layer of sedimentary rock laid down at a particular time in the past.

stretch receptor A modified muscle cell embedded in the connective tissue of a muscle that acts as a mechanoreceptor in response to stretching of that muscle.

striated muscle See skeletal muscle.

strobilus (plural: *strobili*) One of several cone-like structures in various groups of plants (including club mosses, horsetails, and conifers) associated with the production and dispersal of reproductive products.

stroma The fluid contents of an organelle such as a chloroplast or mitochondrion.

structural gene A gene that encodes the primary structure of a protein not involved in the regulation of gene expression.

structural isomers Molecules made up of the same kinds and numbers of atoms, in which the atoms are bonded differently.

structural motif A three-dimensional structural element that is part of a larger molecule. For example, there are four common motifs in DNA-binding proteins: helix-turn-helix, zinc finger, leucine zipper, and helix-loop-helix.

style [Gk. *stylos*: pillar or column] In the angiosperm flower, a column of tissue extending from the tip of the ovary, and bearing the stigma or receptive surface for pollen at its apex.

sub- [L. *under*] A prefix used to designate a structure that lies beneath another or is less than another. For example, subcutaneous (beneath the skin); subspecies.

suberin A waxlike lipid that is a barrier to water and solute movement across the Casparian strip of the endodermis.

submucosa (sub *mew* *koe'* *sah*) The tissue layer just under the epithelial lining of the lumen of the digestive tract.

subsoil The soil horizon lying below the topsoil and above the parent rock (bedrock); the zone of infiltration and accumulation of materials leached from the topsoil. Also called the B horizon.

substrate (sub' *strayte*) The molecule or molecules on which an enzyme exerts catalytic action.

substratum (plural: *substrata*) The base material on which a sessile organism lives.

succession The gradual, sequential series of changes in the species composition of a community following a disturbance.

succulence In plants, possession of fleshy, water-storing leaves or stems; an adaptation to dry environments.

superficial cleavage A variation of incomplete cleavage in which cycles of mitosis occur without cell division, producing a syncytium (a single cell with many nuclei).

suprachiasmatic nuclei (SCN) In mammals, two clusters of neurons just above the optic chiasm that act as the master circadian clock.

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface

area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

surface tension The attractive intermolecular forces at the surface of liquid; especially important in water.

surfactant A substance that decreases the surface tension of a liquid. Lung surfactant, secreted by cells of the alveoli, is mostly phospholipid and decreases the amount of work necessary to inflate the lungs.

survivorship (l_x) In life tables, the proportion of individuals in a cohort that are alive at age x . A graph of this data is a survivorship curve.

suspensor In the embryos of seed plants, the stalk of cells that pushes the embryo into the endosperm and is a source of nutrient transport to the embryo.

sustainable Pertaining to the use and management of ecosystems in such a way that humans benefit over the long term from specific ecosystem goods and services without compromising others.

symbiosis (sim' *bee oh' sis*) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

symmetry Pertaining to an attribute of an animal body in which at least one plane can divide the body into similar, mirror-image halves. (See bilateral symmetry, radial symmetry.)

sympathetic nervous system The division of the autonomic nervous system that works in opposition to the parasympathetic nervous system. (Contrast with parasympathetic nervous system.)

sympatric speciation (sim *pat' rik*) [Gk. *sym*: same + *patria*: homeland] Speciation due to reproductive isolation without any physical separation of the subpopulation. (Contrast with allopatric speciation.)

symplast The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

symporter A membrane transport protein that carries two substances in the same direction. (Contrast with antiporter, uniporter.)

synapomorphy A trait that arose in the ancestor of a phylogenetic group and is present (sometimes in modified form) in all of its members, thus helping to delimit and identify that group. Also called a shared derived trait.

synapse (sin' *aps*) [Gk. *syn*: together + *haptein*: to fasten] A specialized type of junction where a neuron meets its target cell (which can be another neuron or some other type of cell) and information in the form of neurotransmitter molecules is exchanged across a synaptic cleft.

synapsis (sin *ap' sis*) The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

synergids [Gk. *syn*: together + *ergos*: work] In angiosperms, the two cells accompanying the egg cell at one end of the megagametophyte.

syngamy See fertilization.

synonymous (silent) substitution A change of one nucleotide in a sequence to another when that change does not affect the amino acid specified (i.e., UUA → UUG, both specifying leucine). (Contrast with nonsynonymous substitution, missense substitution, nonsense substitution.)

systematics The scientific study of the diversity and relationships among organisms.

systemic acquired resistance A general resistance to many plant pathogens following infection by a single agent.

systemic circuit Portion of the circulatory system by which oxygenated blood from the lungs or gills is distributed throughout the rest of the body and returned to the heart. (Contrast with pulmonary circuit.)

systems biology The scientific study of an organism as an integrated and interacting system of genes, proteins, and biochemical reactions.

systole (sis' *tuh lee*) [Gk. *syntole*: contraction] Contraction of a chamber of the heart, driving blood forward in the circulatory system. (Contrast with diastole.)

- T -

T cell A type of lymphocyte involved in the cellular immune response. The final stages of its development occur in the thymus gland. (Contrast with B cell; see also cytotoxic T cell, T-helper cell.)

T cell receptor A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

T-helper cell (T_H) Type of T cell that stimulates events in both the cellular and humoral immune responses by binding to the antigen on an antigen-presenting cell; target of the HIV-I virus, the agent of AIDS. (Contrast with cytotoxic T cells.)

T tubules A system of tubules that runs throughout the cytoplasm of a muscle fiber, through which action potentials spread.

taproot system A root system typical of eudicots consisting of a primary root (*taproot*) that extends downward by tip growth and outward by initiating lateral roots. (Contrast with fibrous root system.)

target cell A cell with the appropriate receptors to bind and respond to a particular hormone or other chemical mediator.

taste bud A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

TATA box An eight-base-pair sequence, found about 25 base pairs before the starting point for transcription in many eukaryotic promoters, that binds a transcription factor and thus helps initiate transcription.

taxon (plural: *taxa*) [Gk. *taxis*: arrange, put in order] A biological group (typically a species or a clade) that is given a name.

telencephalon The outer, surrounding structure of the embryonic vertebrate forebrain, which develops into the cerebrum.

telomerase An enzyme that catalyzes the addition of telomeric sequences lost from chromosomes during DNA replication.

telomeres (tee' *lo merz*) [Gk. *telos*: end + *meros*: units, segments] Repeated DNA sequences at the ends of eukaryotic chromosomes.

telophase (tee' *lo phase*) [Gk. *telos*: end] The final phase of mitosis or meiosis during which chromosomes became diffuse, nuclear envelopes reform, and nucleoli begin to reappear in the daughter nuclei.

template A molecule or surface on which another molecule is synthesized in complementary fashion, as in the replication of DNA.

template strand In double-stranded DNA, the strand that is transcribed to create an RNA transcript that will be processed into a protein. Also

refers to a strand of RNA that is used to create a complementary RNA.

temporal summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations or hyperpolarizations produced by rapidly repeated stimulation of a single point on the postsynaptic cell. (Contrast with spatial summation.)

tendon A collagen-containing band of tissue that connects a muscle with a bone.

tepal A sterile, modified, nonphotosynthetic leaf of an angiosperm flower that cannot be distinguished as a petal or a sepal.

termination In molecular biology, the end of transcription or translation.

terminator A sequence at the 3' end of mRNA that causes the RNA strand to be released from the transcription complex.

terrestrial (ter res' tree al) [L. *terra*: earth] Pertaining to or living on land. (Contrast with aquatic, marine.)

tertiary structure In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, secondary, and quaternary structures.)

test cross Mating of a dominant-phenotype individual (who may be either heterozygous or homozygous) with a homozygous-recessive individual.

testis (tes' tis) (plural: testes) [L. *testis*: witness] The male gonad; the organ that produces the male gametes.

tetanus [Gk. *tetanos*: stretched] (1) A state of sustained maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often fatal disease ("lockjaw") caused by the bacterium *Clostridium tetani*.

tetrad [Gk. *tettas*: four] During prophase I of meiosis, the association of a pair of homologous chromosomes or four chromatids.

thalamus [Gk. *thalamos*: chamber] A region of the vertebrate forebrain; involved in integration of sensory input.

theory [Gk. *theoria*: analysis of facts] A far-reaching explanation of observed facts that is supported by such a wide body of evidence, with no significant contradictory evidence, that it is scientifically accepted as a factual framework. Examples are Newton's theory of gravity and Darwin's theory of evolution. (Contrast with hypothesis.)

thermoneutral zone [Gk. *thermos*: temperature] The range of temperatures over which an endotherm does not have to expend extra energy to thermoregulate.

thermophile (ther' muh fyle) [Gk. *thermos*: temperature + *philos*: loving] An organism that lives exclusively in hot environments.

thoracic cavity [Gk. *thorax*: breastplate] The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

thoracic duct The connection between the lymphatic system and the circulatory system.

threshold The level of depolarization that causes an electrically excitable membrane to fire an action potential.

thrombus (throm' bus) [Gk. *thrombos*: clot] A blood clot that forms within a blood vessel and remains attached to the wall of the vessel. (Contrast with embolus.)

thylakoid (thigh la koid) [Gk. *thylakos*: sack or pouch] A flattened sac within a chloroplast. Thylakoid membranes contain all of the chlorophyll in a plant, in addition to the electron carriers of photophosphorylation. Thylakoids stack to form grana.

thymine (T) Nitrogen-containing base found in DNA.

thymus [Gk. *thymos*: warty] A ductless, glandular lymphoid tissue, involved in development of the immune system of vertebrates. In humans, the thymus degenerates during puberty.

thyroid gland [Gk. *thyreos*: door-shaped] A two-lobed gland in vertebrates. Produces the hormone thyroxine.

thyrotropin Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyroid-stimulating hormone (TSH).

thyrotropin-releasing hormone (TRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to release thyrotropin.

thyroxine Hormone produced by the thyroid gland; controls many metabolic processes.

tidal volume The amount of air that is exchanged during each breath when a person is at rest.

tight junction A junction between epithelial cells in which there is no gap between adjacent cells.

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

tissue system In plants, any of three organized groups of tissues—dermal tissue, vascular tissue, and ground tissue—that are established during embryogenesis and have distinct functions.

titin A protein that holds bundles of myosin filaments in a centered position within the sarcomeres of muscle cells. The largest protein in the human body.

tonoplast The membrane of the plant central vacuole.

topsoil The uppermost soil horizon; contains most of the organic matter of soil, but may be depleted of most mineral nutrients by leaching. Also called the A horizon.

totipotent [L. *toto*: whole, entire + *potens*: powerful] Possessing all the genetic information and other capacities necessary to form an entire individual. (Contrast with multipotent, pluripotent.)

trachea (tray' kee ah) [Gk. *trakhoia*: tube] A tube that carries air to the bronchi of the lungs of vertebrates. When plural (*tracheae*), refers to the major airways of insects.

tracheary element Either of two types of xylem cells—tracheids and vessel elements—that undergo apoptosis before assuming their transport function.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

trade-off The relationship between the fitness benefits conferred by an adaptation and the fitness costs it imposes. For an adaptation to be favored by natural selection, the benefits must exceed the costs.

trait In genetics, a specific form of a character: eye color is a character; brown eyes and blue eyes are traits. (Contrast with character.)

transcription The synthesis of RNA using one strand of DNA as a template.

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

transduction (1) Transfer of genes from one bacterium to another by a bacteriophage. (2) In sensory cells, the transformation of a stimulus (e.g., light energy, sound pressure waves, chemical or electrical stimulants) into action potentials.

transfection Insertion of recombinant DNA into animal cells.

transfer RNA (tRNA) A family of double-stranded RNA molecules. Each tRNA carries a specific amino acid and anticodon that will pair with the complementary codon in mRNA during translation.

transformation (1) A mechanism for transfer of genetic information in bacteria in which pure DNA from a bacterium of one genotype is taken in through the cell surface of a bacterium of a different genotype and incorporated into the chromosome of the recipient cell. (2) Insertion of recombinant DNA into a host cell.

transgenic Containing recombinant DNA incorporated into the genetic material.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

transmembrane protein An integral membrane protein that spans the phospholipid bilayer.

transpiration [L. *spirare*: to breathe] The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus mineral nutrients) from the roots.

transpiration-cohesion-tension mechanism Theoretical basis for water movement in plants: evaporation of water from cells within leaves (transpiration) causes an increase in surface tension, pulling water up through the xylem. Cohesion of water occurs because of hydrogen bonding.

transposable element A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

transposon Mobile DNA segment that can insert into a chromosome and cause genetic change.

triglyceride A simple lipid in which three fatty acids are combined with one molecule of glycerol.

triploblastic Having three cell layers.

trisomic Containing three rather than two members of a chromosome pair.

tRNA See transfer RNA.

trochophore (troke' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

trophic cascade The progression over successively lower trophic levels of the indirect effects of a predator.

trophic level [Gk *trophes*: nourishment] A group of organisms united by obtaining their energy from the same part of the food web of a biological community.

trophoblast [Gk *trophes*: nourishment + *blastos*: sprout] At the 32-cell stage of mammalian development, the outer group of cells that will become part of the placenta and thus nourish the growing embryo. (Contrast with inner cell mass.)

tropic hormones Hormones produced by the anterior pituitary that control the secretion of hormones by other endocrine glands.

tropomyosin [troe poe my' oh sin] One of the three protein components of an actin filament; controls the interactions of actin and myosin necessary for muscle contraction.

tropinin One of the three components of an actin filament; binds to actin, tropomyosin, and Ca^{2+} .

troposphere The lowest atmospheric zone, reaching upward from the Earth's surface approximately 10–17 km. Zone in which virtually all water vapor is located.

true-breeding A genetic cross in which the same result occurs every time with respect to the trait(s) under consideration, due to homozygous parents.

trypsin A protein-digesting enzyme. Secreted by the pancreas in its inactive form (trypsinogen), it becomes active in the duodenum of the small intestine.

tubulin A protein that polymerizes to form microtubules.

tumor [L. *tumor*: a swollen mass] A disorganized mass of cells. Malignant tumors spread to other parts of the body.

tumor necrosis factor A family of cytokines (growth factors) that causes cell death and is involved in inflammation.

tumor suppressor A gene that codes for a protein product that inhibits cell proliferation; inactive in cancer cells. (Contrast with oncogene.)

turgor pressure [L. *turgidus*: swollen] See pressure potential.

turnover In freshwater ecosystems, vertical movements of water that bring nutrients and dissolved CO_2 to the surface and O_2 to deeper water.

tympenic membrane [Gk. *tympanum*: drum] The eardrum.

- U -

ubiquinone (yoo bic' kwi known) [L. *ubique*: everywhere] A mobile electron carrier of the mitochondrial respiratory chain. Similar to plastoquinone found in chloroplasts.

ubiquitin A small protein that is covalently linked to other cellular proteins identified for breakdown by the proteasome.

ultimate cause In ethology, the evolutionary processes that produced an animal's capacity and tendency to behave in particular ways. (Contrast with proximate cause.)

uniporter [L. *unus*: one + *portal*: doorway] A membrane transport protein that carries a single substance in one direction. (Contrast with antiporter, symporter.)

unsaturated fatty acid A fatty acid whose hydrocarbon chain contains one or more double bonds. (Contrast with saturated fatty acid.)

upregulation A process by which the abundance of receptors for a hormone increases when

hormone secretion is suppressed. (Contrast with downregulation.)

upwelling zones Areas of the ocean where cool, nutrient-rich water from deeper layers rises to the surface.

uracil (U) A pyrimidine base found in nucleotides of RNA.

urea A compound that is the main excreted form of nitrogen by many animals, including mammals.

ureotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is urea. (Contrast with ammonotelic, uricotelic.)

ureter (your' uh tur) Long duct leading from the vertebrate kidney to the urinary bladder or the cloaca.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

uric acid A compound that serves as the main excreted form of nitrogen in some animals, particularly those which must conserve water, such as birds, insects, and reptiles.

uricotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is uric acid. (Contrast with ammonotelic, ureotelic.)

urinary bladder A structure in which urine is stored until it can be excreted to the outside of the body.

urine (you' rin) In vertebrates, the fluid waste product containing the toxic nitrogenous by-products of protein and amino acid metabolism.

uterine cycle In human females, the monthly cycle of events by which the endometrium is prepared for the arrival of a blastocyst. (Contrast with ovarian cycle.)

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

- V -

vaccination Injection of virus or bacteria or their proteins into the body, to induce immunization. The injected material is usually attenuated (weakened) before injection.

vacuole (vac' yew ole) Membrane-enclosed organelle in plant cells that can function for storage, water concentration for turgor, or hydrolysis of stored macromolecules.

vagina (vuh jine' uh) [L. *sheath*] In female animals, the entry to the reproductive tract.

van der Waals forces Weak attractions between atoms resulting from the interaction of the electrons of one atom with the nucleus of another. This type of attraction is about one-fourth as strong as a hydrogen bond.

variable region The portion of an immunoglobulin molecule or T-cell receptor that includes the antigen-binding site and is responsible for its specificity. (Contrast with constant region.)

vas deferens (plural: vasa deferentia) Duct that transfers sperm from the epididymis to the urethra.

vasa recta Blood vessels that parallel the loops of Henle and the collecting ducts in the renal medulla of the kidney.

vascular (vas' kew lar) [L. *vasculum*: a small vessel] Pertaining to organs and tissues that conduct fluid, such as blood vessels in animals and xylem and phloem in plants.

vascular bundle In vascular plants, a strand of vascular tissue, including xylem and phloem as well as thick-walled fibers.

vascular cambium (kam' bee um) [L. *cambiare*: to exchange] In plants, a lateral meristem that gives rise to secondary xylem and phloem.

vascular tissue system The transport system of a vascular plant, consisting primarily of xylem and phloem.

vasopressin See antidiuretic hormone.

vector (1) An agent, such as an insect, that carries a pathogen affecting another species. (2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

vegetal hemisphere The lower portion of some animal eggs, zygotes, and embryos, in which the dense nutrient yolk settles. The *vegetal pole* is to the very bottom of the egg or embryo. (Contrast with animal hemisphere.)

vegetative Nonreproductive, nonflowering, or asexual.

vegetative meristem An apical meristem that produces leaves.

vegetative reproduction Asexual reproduction through the modification of stems, leaves, or roots.

vein [L. *vena*: channel] A blood vessel that returns blood to the heart. (Contrast with artery.)

ventral [L. *venter*: belly, womb] Toward or pertaining to the belly or lower side. (Contrast with dorsal.)

ventricle A muscular heart chamber that pumps blood through the lungs or through the body.

venule A small blood vessel draining a capillary bed that joins others of its kind to form a vein. (Contrast with arteriole.)

vernalization [L. *vernalis*: spring] Events occurring during a required chilling period, leading eventually to flowering.

vertebral column [L. *vertere*: to turn] The jointed, dorsal column that is the primary support structure of vertebrates.

very low-density lipoproteins (VLDLs) Lipoproteins that consist mainly of triglyceride fats, which they transport to fat cells in adipose tissues throughout the body; associated with excessive fat deposition and high risk for cardiovascular disease.

vesicle Within the cytoplasm, a membrane-enclosed compartment that is associated with other organelles; the Golgi complex is one example.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

vestibular system (ves tib' yew lar) [L. *vestibulum*: an enclosed passage] Structures within the inner ear that sense changes in position or momentum of the head, affecting balance and motor skills.

vicariant event (vye care' ee unt) [L. *vicus*: change] The splitting of a taxon's range by the imposition of some barrier to dispersal.

villus (vil' lus) (plural: villi) [L. *villus*: shaggy hair or beard] A hairlike projection from a membrane; for example, from many gut walls.

virion (veer' e on) The virus particle, the minimum unit capable of infecting a cell.

virulence [L. *virus*: poison, slimy liquid] The ability of a pathogen to cause disease and death.

virus Any of a group of ultramicroscopic particles constructed of nucleic acid and protein (and, sometimes, lipid) that require living cells in order to reproduce. Viruses evolved multiple times from different cellular species.

vital capacity The maximum capacity for air exchange in one breath; the sum of the tidal volume and the inspiratory and expiratory reserve volumes.

vitamin [L. *vita*: life] An organic compound that an organism cannot synthesize, but nevertheless requires in small quantities for normal growth and metabolism.

vitelline envelope The inner, proteinaceous protective layer of a sea urchin egg.

viviparity (vye vi par' uh tee) Reproduction in which fertilization of the egg and development of the embryo occur inside the mother's body. (Contrast with oviparity.)

vivipary Premature germination in plants.

voltage-gated channel A type of gated channel that opens or closes when a certain voltage exists across the membrane in which it is inserted.

vomerinasal organ (VNO) Chemosensory structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals. Often specialized for detecting pheromones.

- W -

water potential In osmosis, the tendency for a system (a cell or solution) to take up water from pure water through a differentially permeable membrane. Water flows toward the system with a more negative water potential. (Contrast with solute potential, pressure potential.)

water vascular system In echinoderms, a network of water-filled canals that functions in gas exchange, locomotion, and feeding.

wavelength The distance between successive peaks of a wave train, such as electromagnetic radiation.

weathering The mechanical and chemical processes by which rocks are broken down into soil particles.

Wernicke's area A region in the temporal lobe of the human brain that is involved with the sensory aspects of language.

white blood cells Cells in the blood plasma that play defensive roles in the immune system. Also called leukocytes.

white matter In the central nervous system, tissue that is rich in axons. (Contrast with gray matter.)

wild-type Geneticists' term for standard or reference type. Deviants from this standard, even if the deviants are found in the wild, are usually referred to as mutant. (Note that this terminology is not usually applied to human genes.)

wood Secondary xylem tissue.

- X -

xerophyte (zee' row fyte) [Gk. *xerox*: dry + *phyton*: plant] A plant adapted to an environment with limited water supply.

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

- Y -

yolk [M.E. *ylke*: yellow] The stored food material in animal eggs, rich in protein and lipids.

yolk sac In reptiles, birds, and mammals, the extraembryonic membrane that forms from the endoderm of the hypoblast; it encloses and digests the yolk.

- Z -

zeaxanthin A blue-light receptor involved in the opening of plant stomata.

zona pellucida A jellylike substance that surrounds the mammalian ovum when it is released from the ovary.

zoospore (zoe' o spore) [Gk. *zoon*: animal + *spora*: seed] In algae and fungi, any swimming spore. May be diploid or haploid.

zygote (zye' gote) [Gk. *zygotos*: yoked] The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

zymogen The inactive precursor of a digestive enzyme; secreted into the lumen of the gut, where a protease cleaves it to form the active enzyme.
